FACULTY OF GRADUATE STUDIES AND RESEARCH

The undersigned certify that they have read, and recommend to the Faculty of Graduate Studies and Research, for acceptance, a thesis entitled "Optimal Process Operation in the Face of Uncertainty" submitted by Linda C. Biswanger in partial fulfilment of the requirements for the degree of Master of Science.

Date *October 3, 1972*.....

## Abstract

An approach to the problem of optimal operation of an existing processing system in the face of uncertainty was suggested. An intrinsic concept is the restriction of the study to overall process relationships and operating conditions, leaving the optimization of individual unit operation for later, more detailed, studies as the need arises.

A simple, mathematically tractable, model of overall relationships is developed, enabling deterministic optimization with a minimum of effort. Critical features of the model are identified, and the extent of uncertainty about those features expressed quantitatively. The implications of uncertainty are recognized, particularly with reference to the choice of optimal operating conditions. A quantitative estimate of the expected cost of uncertainty, the value of removing all uncertainty from the decision, is made.

An analysis of the butadiene section of a synthetic rubber plant was used to illustrate the procedure. A Nagiev model of the process was readily

optimized with the help of nonlinear pattern search and linear programming. Critical uncertain parameters were identified and then treated as random variables characterized by subjective probability distributions. A set of guidelines for process operation in the face of uncertainty were developed to replace a rigid specification of operating conditions. Monte Carlo simulation was used to estimate the expected cost of uncertainty.

## ACKNOWLEDGEMENTS

I wish to thank Dr. D. Quon for his unfailing guidance, helpful criticism and inexhaustable patience throughout our association, and the National Research Council of Canada and the Department of Chemical Engineering for their financial assistance.

Thanks are due to my husband for his understanding and support, both moral and financial, and to Dr. W. Nader for his encouragement.

My thanks are also extended to the many people who were instrumental in the final preparation of the thesis, particularly to (Mrs.) Shirley Morihira, Janice Biswanger, and Mr. and Mrs. Tony Braun.

## I. INTRODUCTION

Since the Industrial Revolution, man has become increasingly dependent on the development and implementation of a rapidly expanding technology to meet his needs and fulfill his desires. The result has been the evolution of the modern industrial nation. Because a major sector of the nation's economy is supported by industry based on some type of processing, the efficient design and operation of processing systems is vital.

Rudd and Watson, in their text (1), have discussed many of the problems encountered in a process engineering study. They define a processing system as a "collection of equipment which effects the transformation of materials through chemical reaction, phase transition, heating and cooling, agglomeration, size reduction, separation, extraction, combustion and so forth". Processing systems range in size and complexity from the basement still to the large commercial systems. The smaller systems are relatively simple and easily exploited. However, as size and complexity increase, more extensive analysis is required to achieve an effective system.

The larger system is more complicated internally and subject to numerous external restrictions. Resources are limited and investment considerable. The system must satisfy many, often conflicting, objective criteria. It is no longer sufficient to accept any system which produces at a profit; some effort must be made to find the system which best achieves the objectives set for it. This latter is the province of optimization theory. An excellent discussion of the organization, techniques and practical aspects of optimization studies, with particular reference to process optimization studies, can be found in Beveridge and Schechter's recent text on the subject (2).

This work is primarily concerned with the optimal operation of existing chemical processing systems. When the system exists, the equipment characteristics and configuration are already set; the investment is fixed. To some extent, the operation of the system has been observed and is known. Solving this process optimization problem implies choosing a set of operating variables so as to optimize some selection criterion while satisfying all internal and external constraints on the system. A comparable

problem arises in the more complex system design studies. A similar analysis is carried out during evaluation of alternate configurations and levels of investment. It is complicated by the need to determine optimal design variables as well as optimal operating variables. Sargent (3) has done a survey and discussion to techniques available for integrated design and optimization of processes. Many of these are applicable to process operation problems as well.

A process optimization study of an existing processing system seeks to improve the operation of the system. The first step in the analysis is the definition of the objective criterion. Most often the intention is to maximize profit and minimize capital investment while meeting all restrictions on the process. When the system exists, investment value is fixed and can be omitted if relative values are used. Sometimes technical criteria are used; normally these can be reduced to some form of economic criteria.

For optimization to take place, the objective criterion must be expressed as a function of the controllable system variables. This step is facilitated by preparing an adequate representation of the system.

The overall structure of the system can be

represented by a block diagram or flowsheet. Each block or process unit represents a portion of the process with one or more specific functions, varying in scope from a distillation tray to an oil refinery, depending on the particular optimization problem. The system consists of a set of process units, interconnected by process streams, which receives input streams and produces output streams.

To evaluate the objective function, the states of the input, output and interlinking streams, and the behavior of the process units, must be defined; the system variables must be specified. Because the variables are inter-related, they cannot all be specified independently, and a model of the behavior of the system, a definition of the relationship between system variables, is required.

The behavior of each process unit is represented by a model. It can be either analytical or empirical; it can be derived from theoretical considerations, or from observed behavior. The model takes the form of a transformation equation which expresses, unambiguously, the unit output variables in terms of unit input variables and process unit characteristics. When the

system exists, most process unit characteristics are defined though a few might remain variable.

The system model is composed of all the individual unit models. With it, the dependent system variables can be determined once the controllable, or decision variables are specified. Because the transformation equations are, in general, difficult to invert, the decision variables are usually chosen from the set of input variables and variable process characteristics.

A processing system is not independent of external influences which can either specify the value or limit the range of variation of the system variables. Restrictions on the design and operation of a processing system arising from external considerations include feedstock and product availability and quality, minimum profit and maximum investment levels, and limits on the production, composition, and disposal of waste products. The system is also subject to restrictions which arise from internal considerations. These are usually constraints on process unit design and operation and include unit dimensions and capacity, acceptable ranges of operating conditions such as flow rates and temperatures, and mass and energy conservation requirements.

For existing systems, these constraints restrict the behavior of the system to feasible modes of operation. The system is also subject to constraints arising from the system modelling procedure. The available data or the form of the model used can restrict the validity of the model to a limited region. These restrictions must be considered in the optimization study to ensure useful results.

Once the system model has been formulated, and the restrictions on system variables identified, the objective function can be finalized. The objective criterion is broken down into components and each component is expressed in terms of technical data, the system variables, available from the system model. This step can be rather complex, particularly in the case of the economic criterion which includes capital costs and the time value of money. For existing systems, the economic objective function is simpler to formulate; only incremental costs need be included.

The optimization model consists of an objective function expressed in terms of system variables, a system model which defines the relationship between the system variables, and a set of restrictions which limits the acceptable range of those variables. Care must be taken

throughout the development of the model to ensure that the model does indeed represent the system.

Once the optimization model has been formulated, only a few more steps prior to the actual optimization remain: derivation of an acceptable solution procedure, simplification of the model if necessary, and verification of the model.

Optimization cannot proceed unless acceptable solutions to the model equations can be found with reasonable ease. When obtaining a solution is inordinately difficult or time-consuming, an unwarranted effort might be required for optimization. If no acceptable solution procedure can be found, the optimization model must be simplified or the project abandoned.

Simplification can be accomplished in several ways. The number of variables in the problem can be reduced by treating those which have a negligible effect on the objective function value as fixed constants. In some cases, the number of equations can be reduced by solving the problem in stages. It may also be possible to reformulate the model and reduce the problem to one of the special cases for which efficient solution procedures exist.

Whatever optimization model is finally adopted,

if the realism of the model is not preserved, optimization would be worthless. Before optimization begins, the optimization model should be verified as well as is possible by comparing the observed or expected behavior of the system with the behavior predicted by the model.

Given a suitable optimization model, optimal operating conditions for the processing system can be found with the help of an appropriate optimization technique. The results of the optimization study will not only indicate optimal operating conditions for the processing system, but also provide insight into any weakness of the optimization model. If necessary, revisions can be made and optimization repeated until acceptable results are obtained.

Optimization theory has been most effective for the design and operation of individual components of processing systems. The optimization model for components is relatively simple, having few variables and few equations. A solution is usually easily obtained, and several effective techniques are available for optimization (2).

Unfortunately, optimization of large processing systems is not as readily accomplished. Developing a

system model from a detailed examination of each process unit results in a large, often nonlinear, system of equations in many variables. Computer simulations such as PACER (4), are typical. Process optimization based on such a model is complicated, if not impossible. The solution of a large nonlinear programming problem is required; no generally applicable approach exists. Most of the available techniques for optimization of large systems (5) are based on decomposition of the problem into several smaller subproblems, taking advantage of the structure of the optimization model. Before one of these methods can be applied, the optimization model must have the appropriate form; modifications might be necessary. Case studies illustrating the application of two decomposition methods, partition programming (6) and Lasdon's multilevel technique (7), support this conclusion: considerable computational effort is required for the successful optimization of a large processing system using a detailed model; the procedure is lengthy and expensive, even with the aid of modern computers.

An alternate approach is to develop an overall, or macroscopic, model of the processing system. Two classes of system variables can be distinguished:

- 1) the strategic variables, which are directly related to overall system behavior (system input and output variables), and process unit interaction, and
- 2) the tactical variables, which pertain to the behavior of individual process units.

The detailed system model discussed previously incorporates both strategic and tactical variables, employing detailed process unit models. Overall relationships are emphasized in the macroscopic model which is concerned primarily with strategic system variables, employing simpler, less representative, process unit models. Each process unit is treated as a black box, or an input-output device. Process unit outputs are expressed in terms of inputs via conversion relations whose coefficients represent, quantitatively, the existing technology of the unit. The conversion relations can be very simple, even linear, as long as the range of the strategic variables, over which the model is valid, is specified. Linear macroscopic models and linear programming were used by Newby and Deam (8) in their studies of refinery problems. Their suggestion has considerable industrial support; indeed, most petroleum refineries make use of linear models for optimization.

The optimization model based on the macroscopic system model would include an objective function expressed in terms of strategic system variables, the restrictions required to ensure feasible and acceptable system variable values, and the restrictions on system variables required to preserve model validity. Optimization based on such a model could be speedily and inexpensively accomplished. In addition, the results of the study could be used to identify the critical areas of the process, pointing out areas where further enrichment is needed, and to provide a framework for later optimization of process unit operation.

Throughout the foregoing discussion, the tacit assumption has been made that the system model developed accurately represents the behavior of the processing system. In practice, this is seldom the case. There will often be uncertainty about the values of some of the system model parameters, arising from unreliable and/or incomplete data as to system response. The approximations made during modelling process unit response may also contribute to the uncertainty. If the uncertainty is ignored, the operating conditions accepted as best on the basis of the optimization study may be far from optimal. The presence and magnitude of

uncertainties in the system model should be recognized and taken into account before an optimization study is considered complete.

Process optimization under uncertainty can be tackled by "decision analysis" - Howard's (9) term for application of modern decision theory to problems in decision-making under uncertainty. The decision analysis approach is based on the assumption that the uncertain parameters can be treated as random variables with "known" probability distributions. The probability distributions are assigned on the basis of available information, both subjective and objective, and can be thought of as a measure of the state of knowledge about the uncertain parameters.

Howard (10) divides the decision analysis procedure into three phases: deterministic, probabilistic and informational. A decision analysis approach to process optimization under uncertainty can be outlined within his broad framework.

The deterministic phase begins with the construction of the deterministic optimization model: the establishment of relationships describing process behavior, the identification of decision and state variables and any additional restrictions on their value,

and the formulation of an objective function. Model parameters are assigned nominal values and ranges reflecting initial information; decision variables are assigned nominal values on the basis of optimization of the deterministic model. A sensitivity analysis is performed to identify those decision variables and model parameters which have a critical effect on objective function value in the neighborhood of the optimal solution to the deterministic problem. Those variables and parameters showing low sensitivity can be regarded as known for the remainder of the analysis.

The probabilistic phase deals with the effect of uncertainty in critical parameters on the decision problem. Each parameter identified as critical by the sensitivity analysis is assigned a probability distribution consistent with available information. If some of the critical parameters are not independent, their joint probability distributions must be assigned. For the remainder of the analysis, the critical parameters are treated as random variables characterized by their assigned probability distributions.

The decision problem is now stochastic. In general, the risk preference of the decision-maker must be accounted for. Risk preference is encoded in a

utility function which serves to relate monetary value to the value judgement, or utility, of the decision maker. Then, the optimal solution to the stochastic decision problem is chosen according to the decision rule first proposed by von Neumann and Morgenstern (11): maximize the expected utility of the objective function. When the decision maker is indifferent to risk, decisions are based on the expected value of the objective function.

The informational phase is concerned with estimating the value of removing the uncertainty in the model parameters. The estimator used is the expected cost of uncertainty - the expected value of the difference between the value of the strategy chosen as optimal in the probabilistic phase, and the value of the optimal strategy when all parameter values are known with certainty. It provides a measure of the value of obtaining better information about model parameters in order to obtain an improved optimization solution.

The approach to determining optimal operating conditions, outlined in the foregoing pages, is intended to be generally applicable to optimization of existing processing systems, particularly in the first optimiza-

tion stage of analysis. It is discussed in detail in the following pages and illustrated by a case study.

## II. THEORY

In general, the commercial chemical plant is a multicomponent, multiphase processing system composed of interconnected process units, each of which performs one or more operations directed towards the conversion of input streams into desired products. Given an existing plant, it is desired to determine a set of those operating conditions directly affecting overall plant operation which is, in some sense, optimal. Briefly, the procedure suggested here is as follows:

- 1) Develop a simple optimization model, basing it on a macroscopic model of the processing system.
- 2) System modelling is usually hampered by notoriously inadequate data, resulting in uncertainty about model parameters. Incorporate the critical uncertain parameters in the optimization model as random variables.
- 3) The resulting programming problem is stochastic. Find an acceptable solution and hence specify 'optimal' operating conditions.
- 4) Estimate the value of obtaining more information about the crucial uncertain parameters, thus

enabling rational decision-making about model improvement in the hope of improving system operation.

#### A. The System Model

The transformation equations which constitute the system model are, essentially, the material balance equations for the processing system. Nagiev (12,13,14) suggested basing material balance calculations on a linear input-output representation of process behavior. The result was a simple material balance formulation for the general multicomponent, multiunit process with arbitrary, defined recycling. The linear system of equations he derived is identical to the system of transformation equations in the economic input-output models introduced by Leontief (15). Nagiev's work forms the basis for the development of the proposed model.

The model is restricted to representation of steady-state relationships among process units and between the processing system and its environment. The system variables considered to be important to overall operation in this formulation are the component flow-rates in the feed, product and process streams, and the inter-unit recycle fractions. Each process unit is treated as a simple black box, or input-output device,

which alters input streams linearly to produce output streams.

For a processing system consisting of  $n$  distinct interconnected process units with  $m$  chemical components in the process streams, define:

$f(i,k)$  = mass feed of component  $i$  to unit  $k$  from outside the system; an external feed stream.

$g(i,k)$  = total mass flow of component  $i$  to unit  $k$  from process units and external feed streams; the charge or internal feed to unit  $k$ .

$a(i,j,k)$  = mass fraction of the total flow of component  $i$  to unit  $j$  which, after processing, goes to unit  $k$ ; a Nagiev or recovery factor.

$p(i,k)$  = the flow of component  $i$  from unit  $k$  which leaves the system as an external product.

$d(i,k)$  = the mass fraction of the total flow of component  $i$  to unit  $k$  which leaves the system as product; a product recovery factor.

$h(i,k)$  = artificial feed of component  $i$  to

unit k introduced to handle production and disappearance due to reaction.

$s(i,q,k)$  = fraction of the mass flow of component  $q$  to unit  $k$  which appears as component  $i$  in unit  $k$  due to reaction; a reaction conversion factor. A negative factor indicates disappearance.

Where there is no reaction in unit  $k$ , a material balance taken around the entrance to that unit yields, for each component  $i$ ,

$$g(i,k) = f(i,k) + \sum_{j=1}^n a(i,j,k) g(i,j) \quad (\text{II-1})$$

Reaction is accounted for by the addition of an artificial feed (or vent) stream to the reaction unit to represent production and disappearance of components due to reaction, an approach suggested by Rosen (16). The material balance equation (II-1) becomes

$$g(i,k) = f(i,k) + \sum_{j=1}^n a(i,j,k) [g(i,j) + h(i,j)] \quad (\text{II-2})$$

Similarly, the product stream flowrates are defined by

$$p(i,k) = d(i,k) [g(i,k) + h(i,k)] \quad (\text{II-3})$$

Further, the artificial feed,  $h(i,k)$ , can be expressed in terms of process flowrates, yielding

$$h(i,k) = \sum_{q=1}^m s(i,q,k) g(q,k) \quad (\text{II-4})$$

These three equations, (II-2), (II-3), and (II-4) are the basic material balance equations for the processing system. The systems of  $n$  equations which result from writing each equation for all process units are, in matrix-form:

$$\left[ \underline{I} - \underline{A}_i^t \right] \underline{g}_i = \underline{f}_i + \underline{A}_{i-i}^t \underline{h}_i \quad (\text{II-5})$$

$$\text{where } \underline{A}_i^t = \begin{bmatrix} a(i,1,1) & a(i,2,1) & . & . & . & a(i,n,1) \\ a(i,1,2) & a(i,2,2) & . & . & . & a(i,n,2) \\ . & . & . & . & . & . \\ . & . & . & . & . & . \\ a(i,1,n) & a(i,2,n) & . & . & . & a(i,n,n) \end{bmatrix}$$

$$\underline{p}_i = \underline{D}_i [\underline{g}_i + \underline{h}_i] \quad (\text{II-6})$$

where

$$\underline{D}_i = \begin{bmatrix} d(i,1) \\ d(i,2) \\ \cdot \\ \cdot \\ d(i,n) \end{bmatrix}$$

and

$$\underline{h}_i = \sum_{q=1}^m \underline{S}_{i,q} \underline{g} \quad (\text{II-7})$$

where

$$\underline{S}_{i,q} = \begin{bmatrix} s(i,q,1) \\ s(i,q,2) \\ \cdot \\ \cdot \\ s(i,q,n) \end{bmatrix}$$

In the preceding equations, as in those to follow, the notation for vectors of the system variables  $f(i,k)$ ,  $g(i,k)$ ,  $p(i,k)$  and  $h(i,k)$  follows the convention:

$$\underline{g}_i = \begin{bmatrix} g(i,1) \\ g(i,2) \\ \cdot \\ \cdot \\ g(i,n) \end{bmatrix}$$

and

$$\underline{g} = \begin{bmatrix} \underline{g}_1 \\ \underline{g}_2 \\ \cdot \\ \cdot \\ \underline{g}_m \end{bmatrix}$$

Writing the material balance equations for all components results in:

$$\left[ \underline{I} - \underline{A}^t \right] \underline{g} = \underline{f} + \underline{A}^t \underline{h} \quad (\text{II-8})$$

where

$$\underline{A}^t = \begin{bmatrix} \underline{A}_1^t & & & \\ & \underline{A}_2^t & & \\ & & \cdot & \\ & & & \cdot \\ & & & & \underline{A}_m^t \end{bmatrix}$$

$$\underline{p} = \underline{D}[\underline{g} + \underline{h}] \quad (\text{II-9})$$

where

$$\underline{D} = \begin{bmatrix} \underline{D}_1 & & & & \\ & \underline{D}_2 & & & \\ & & \cdot & & \\ & & & \cdot & \\ & & & & \underline{D}_m \end{bmatrix}$$

$$\underline{h} = \underline{S} \underline{g} \quad (\text{II-10})$$

where

$$\underline{S} = \begin{bmatrix} \underline{S}_{1,1} & \underline{S}_{1,2} & \cdot & \cdot & \cdot & \underline{S}_{1,m} \\ \underline{S}_{2,1} & \underline{S}_{2,2} & \cdot & \cdot & \cdot & \underline{S}_{2,m} \\ \cdot & \cdot & & & & \cdot \\ \cdot & \cdot & & & & \cdot \\ \underline{S}_{m,1} & \underline{S}_{m,2} & & & & \underline{S}_{m,m} \end{bmatrix}$$

Substituting equation (II-10) in equations (II-8) and (II-9) yields

$$\left[ \underline{I} - \underline{A}^t - \underline{A}^t \underline{S} \right] \underline{g} = \underline{f} \quad (\text{II-11})$$

$$\underline{p} = \left[ \underline{D} + \underline{D} \underline{S} \right] \underline{g} \quad (\text{II-12})$$

or, if

$$\underline{B} = \underline{I} - \underline{A}^t - \underline{A}^t \underline{S} \quad (\text{II-13})$$

and

$$\underline{T} = \underline{D} + \underline{D} \underline{S} \quad (\text{II-14})$$

equations (II-11) and (II-12) may be written

$$\underline{B} \underline{g} = \underline{f} \quad (\text{II-15})$$

$$\underline{p} = \underline{T} \underline{g} \quad (\text{II-16})$$

Equations (II-15) and (II-16) are general material balance equations for the processing system; they define the relationships between the component flow rates,  $\underline{f}$ ,  $\underline{g}$ , and  $\underline{p}$ , and constitute a system model. When the entries in the matrices  $\underline{A}$ ,  $\underline{S}$  and  $\underline{D}$  are fixed, the equations are linear and easily solved once one of the system flow vectors is specified.

Another factor which is important to overall system behavior, and should be included as a system variable, is inter-unit recycle. Inter-unit recycle can be represented by a separate process unit on the process flowsheet - a simple stream splitter. The

stream splitter is a unit which splits an input stream into two output streams without altering composition; it is characterized by a split factor (or recycle fraction). In the system model presented here, split factors appear as entries in the matrices A and D. When they are variable, the model is nonlinear.

The fractions  $a(i,j,k)$ ,  $s(i,q,k)$  and  $d(i,k)$  are model parameters which represent the technology of individual process units. They can be estimated, usually from data on system operation, in several ways; Nagiev (14) and Vela (17) have discussed some of these. Whatever procedure is used to arrive at technology parameter values, certain restrictions, arising from the parameter definitions and conservation of matter, must be observed.

1) The recovery factors,  $a(i,j,k)$  and  $d(i,j)$  are restricted by

$$d(i,j) + \sum_{k=1}^n a(i,j,k) \leq 1.0 \quad (\text{II-17})$$

$$0.0 \leq d(i,j) \leq 1.0 \quad (\text{II-18})$$

$$0.0 \leq a(i,j,k) \leq 1.0 \quad (\text{II-19})$$

2) The restrictions on the reaction conversion factors  $s(i,q,j)$  are more complex. The following restrictions apply in all cases

$$\sum_{i=1}^n s(i,q,j) \leq 0.0 \quad (\text{II-20})$$

$$s(i,i,j) \leq 0.0 \quad (\text{II-21})$$

If the amount of component  $i$  converted is expressed only in terms of the amount of component  $i$  present in the input charge stream, then

$$s(i,q,j) \geq 0.0 \quad , \quad i \neq q \quad (\text{II-22})$$

and  $|s(i,q,j)| \leq 1.0 \quad (\text{II-23})$

When it is desirable to express conversion of component  $i$  in terms of the input mass of another component, say  $q_b$ , then

$$s(i,q_b,j) < 0.0 \quad \text{for some } q_b = i \quad (\text{II-24})$$

and the following constraint must be added explicitly to the system model.

$$g(i,j) \geq -s(i,q_b,j) g(q_b,j) \quad (\text{II-25})$$

Because this type of constraint complicates the model, it is preferable to restrict reaction conversion factors by equation (II-22) for all components in all reaction units.

#### B. Restrictions on System Variables

The range of variation of the system variables is not unlimited. Constraints arise from external requirements and limitations, the characteristics of process equipment, and the system model. Included in these restrictions are factors such as: feedstock availability and composition, process unit capacities and requirements, product demand and specifications, and model validity limits. To preserve the linearity of the model, each constraint is expressed as a requirement on a linear function of the system flow variables. The set of constraints so defined can be written

$$\begin{array}{c} \underline{\phantom{R_f f}} \\ R_f \underline{f} + R_g \underline{g} + R_p \underline{p} \end{array} \begin{array}{c} < \\ = \\ > \end{array} \underline{\phantom{rhs}} \quad \text{(II-26)}$$

where each constraint takes on only one of the signs from the set  $\{<, =, >\}$ .

The model formulation also implies certain restrictions which must be included explicitly. The variable split factors are required to be positive fractions. If there are  $ns$  variable split factors, this restriction can be written

$$0.0 \leq sf_k \leq 1.0 \quad k=1,2,\dots, ns \quad (II-27)$$

or, in vector form

$$0.0 \leq \underline{sf} \leq 1.0 \quad (II-28)$$

The system flow variables must be positive, that is

$$\underline{f}, \underline{p}, \underline{g} \geq 0.0 \quad (II-29)$$

### C. The Objective Function

In the overall optimization of processing system operation, the most common objective criterion is the minimization of net costs (maximization of net profit). Taking care to preserve linearity, the objective criterion can be expressed in terms of system flow variables in the following form.

$$\text{minimize } z = \underline{c}_f^t \underline{f} + \underline{c}_g^t \underline{g} - \underline{c}_p^t \underline{p} \quad (\text{II-30})$$

The coefficients  $\underline{c}_f$ ,  $\underline{c}_g$  and  $\underline{c}_p$  are cost coefficients corresponding to feedstock costs, operating costs, and product values respectively. Because fixed costs do not affect the operation of an existing process, these are not included in the cost function.

#### D. The Deterministic Decision

The deterministic optimization model consists of the basic system model, the additional constraints defining restrictions on system variables, and the objective function. All model parameters are assumed to be known. If the decision variables are taken to be  $\underline{sf}$  and one of the system flow vectors, usually  $\underline{f}$ , the deterministic optimization problem is the following nonlinear programming problem.

Find  $\underline{f}$ ,  $\underline{sf}$

so as to

$$\text{minimize } z = \underline{c}_f^t \underline{f} + \underline{c}_g^t \underline{g} - \underline{c}_p^t \underline{p} \quad (\text{II-30})$$

subject to:

$$\underline{B} \underline{g} = \underline{f} \quad (\text{II-15})$$

$$\underline{p} = \underline{T} \underline{g} \quad (\text{II-16})$$

$$\underline{R}_f \underline{f} + \underline{R}_g \underline{g} + \underline{R}_p \underline{p} \stackrel{<}{=} \underline{rhs} \quad (\text{II-26})$$

$$0.0 \leq \underline{sf} \leq 1.0 \quad (\text{II-28})$$

$$\underline{f}, \underline{p}, \underline{g}, \geq 0.0 \quad (\text{II-29})$$

The above problem can be considerably reduced in size by elimination of the dependent variables from the objective function and process constraints. Using equations (II-15) and (II-16),  $\underline{g}$  and  $\underline{p}$  are expressed in terms of  $\underline{f}$  and the technology coefficient matrices,  $\underline{B}$  and  $\underline{T}$ .

$$\underline{g} = \underline{B}^{-1} \underline{f} \quad (\text{II-31})$$

$$\underline{p} = \underline{T} \underline{g} = \underline{T} \underline{B}^{-1} \underline{f} \quad (\text{II-32})$$

Using these relations to eliminate  $\underline{p}$  and  $\underline{g}$ , the reduced problem can be stated.

find  $\underline{f}$ ,  $\underline{sf}$

so as to

$$\text{minimize } z = \left[ \underline{c}_f^t + \underline{c}_g^t \underline{B}^{-1} - \underline{c}_p^t \underline{T} \underline{B}^{-1} \right] \underline{f} \quad (\text{II-33})$$

subject to

$$\left[ \underline{R}_f + \underline{R}_g \underline{B}^{-1} + \underline{R}_p \underline{T} \underline{B}^{-1} \right] \underline{f} \begin{matrix} < \\ = \\ > \end{matrix} \underline{rhs} \quad (\text{II-34})$$

$$0.0 \leq \underline{sf} \leq 1.0 \quad (\text{II-28})$$

$$\underline{f} \geq 0.0 \quad (\text{II-29})$$

When  $\underline{sf}$  is also fixed, the optimization problem is linear and can be efficiently solved by using a standard linear programming algorithm in conjunction with the reduced form of the deterministic decision problem.

The general nonlinear programming problem can be solved with the help of separable programming (18). The nonlinear terms in the system model are first converted to separable form by transformation of variables and then approximated by piecewise linear

functions. The original, unreduced form of the problem must be used, and each linear approximation requires the addition of several new variables and constraints to the problem.

When there are few variable split factors an alternate approach is easier to formulate and could be more efficient. The suggestion is to use a search technique to find optimal values for the split factors, employing linear programming and the reduced form of the problem to solve for optimal flow rates at each step. The nonlinear programming problem then has the following form.

Find  $\underline{sf}$

so as to

$$\text{minimize } z = \left[ \underline{c}_f^t + \underline{c}_g^t \underline{B}^{-1} - \underline{c}_p^t \underline{T} \underline{B}^{-1} \right] \underline{f} \quad (\text{II-33})$$

subject to

$$0.0 \leq \underline{sf} \leq 1.0 \quad (\text{II-28})$$

$\underline{f} = \underline{f}_s$  chosen so as to

$$\text{minimize } z_s = \left[ \underline{c}_f^L + \underline{c}_g^T \underline{B}^{-1} - \underline{c}_p^T \underline{B}^{-1} \right] \underline{f}_s \quad (\text{II-33})$$

subject to

$$\left[ \underline{R}_f + \underline{R}_g \underline{B}^{-1} + \underline{R}_p^T \underline{B}^{-1} \right] \underline{f}_s \begin{matrix} < \\ = \\ > \end{matrix} \underline{rhs} \quad (\text{II-34})$$

$$\underline{f}_s \geq 0.0 \quad (\text{II-29})$$

The search technique used must be one which does not require explicit gradient information. The pattern search method developed by Hooke and Jeeves (19) appears to be suitable. It is easily programmed (20) and is reliable as a general technique (21).

Neither nonlinear optimization technique guarantees location of global optima; care must be taken to avoid stopping at a local optimum.

## E. Sensitivity Analysis

### 1. Model Parameters

A fundamental assumption in the formulation of the deterministic optimization model was that all system model parameters were known. In practice,

because of inadequate data, they are not known with certainty. When an uncertain parameter is crucial to the model's representation of process behavior, it may have considerable effect on the optimal solution and objective function value. A sensitivity analysis is performed to determine which of the parameters are critical.

Associated with each parameter is a nominal value, the value assigned for the deterministic model, and an interval, the assumed range of the parameter, which reflect initial information about the parameter. If the uncertain parameter is thought of as being a random variable, the nominal value might correspond to the mean or the mode of the distribution, and the range might correspond to the 10 and 90 percent points on the cumulative distribution function. A sensitivity analysis consists of varying each uncertain parameter over its range, or a fixed portion of its range, and observing the resulting change in objective function value relative to some reference point. If some model parameters are not independently defined, their joint sensitivity must be examined.

Demski (22) has discussed some of the theoretical limitations of sensitivity analysis which should be kept under consideration.

1) Parameter deviations can interact; the sensitivity analysis assumes they do not. A joint sensitivity analysis could be used to help take this into account, but such an analysis might require an inordinate effort.

2) A parameter is identified as sensitive only with reference to the existing model structure and parameter estimates, for a particular decision. The sensitive parameter set may not be stable for parameter and structural deviations.

3) In large models, because the number of parameters which can reasonably be examined is limited, a complete analysis is not possible.

4) The results are model dependent; they are applicable to the real system only in so far as the model accurately represents the system.

If these limitations are considered during the interpretation of the results, the following simple procedure is adequate for sensitizing the macroscopic optimization model. Each uncertain parameter is perturbed, in proportion to its range, about its nominal value and the effect on the objective function value observed. The reference

decision is the solution to the deterministic problem defined by using nominal values for model parameters. In the macroscopic system model presented here very few of the model parameters can be varied independently. Equations (II-17) and (II-20) define joint relationships which must be taken into account in the perturbations. In consequence, when a parameter is identified as sensitive, there may actually be other parameters associated with it which contribute to its critical nature. The critical parameters identified by this sensitivity analysis are those sensitive parameters or groups of parameters which, when perturbed, result in an objective function value change greater than some stipulated acceptable variation.

## 2. Split Factors

Each variable split factor adds to the computational effort required to solve the optimization problem. It would be advantageous to treat them as fixed constants at the level found to be optimal for the deterministic optimization model. This step is justified if it can be shown that such a move would not appreciably affect the optimal solution and objective function value.

A sensitivity analysis aimed at determining which, if any, split factors are not critical is accomplished in two steps.

1) Perturb each split factor and observe the effect on objective function value, as was done for model parameters. Those split factors exhibiting negligible effect on objective function value can be treated as fixed constants.

2) The remaining split factors are critical if their ranges are those assumed during step 1. A simple check can be made. Each model parameter or group of parameters found to be critical is perturbed as in the previous sensitivity analysis, and the optimal solution to the resulting nonlinear programming problem found. If a split factor shows no appreciable variation in its optimal value, it may be treated as a fixed constant.

#### F. Encoding Uncertainty

Each of the model parameters identified as critical is assigned a probability distribution in accord with the state of knowledge about the parameter. If no more conclusive information is available, opinion analysis can be used to compile appropriate probability

distributions (22). Of course, the distributions assigned should be consistent with the range and nominal value information assumed earlier; if not, the sensitivity of the affected parameters should be re-examined. The critical parameters are treated as random variables characterized by their assigned distributions for the remainder of the analysis.

Because there is uncertainty about some model parameters, the decision problem is stochastic, and there is risk associated with the choice of an operating strategy. However, management usually acts as if it were indifferent to risk at the low levels of investment normally required for process operation. The high risk capital investment has already been made; once the plant is in existence, the primary concern is in maximizing profit. Consequently, the profit for the processing system is an acceptable estimate of management's utility and the optimal strategy can be selected on the basis of maximizing the expected profit, or minimizing the expected cost.

#### G. The Stochastic Decision

The optimality criterion for the stochastic decision problem is that the expected value of the

cost function be minimized; that is

$$\text{minimize } \mu_z = \underline{c}_f^t \underline{\mu}_f + \underline{c}_g^t \underline{\mu}_g - \underline{c}_p^t \underline{\mu}_p \quad (\text{II-35})$$

where  $\mu_z$  denotes the expected value of  $z$  and the vectors  $\underline{\mu}_f$ ,  $\underline{\mu}_g$  and  $\underline{\mu}_p$  are the expected values of the flow rate vectors  $\underline{f}$ ,  $\underline{g}$  and  $\underline{p}$ . Because one of the flow rate vectors, say  $\underline{f}$ , will be a decision vector with a specified value,

$$\underline{\mu}_f = \underline{f} \quad (\text{II-36})$$

and hence, the optimality criterion can be rewritten as

$$\text{minimize } \mu_z = \underline{c}_f^t \underline{f} + \underline{c}_g^t \underline{\mu}_g - \underline{c}_p^t \underline{\mu}_p \quad (\text{II-37})$$

Given the optimality criterion, the stochastic decision problem can be stated formally as

find  $\underline{f}$ ,  $\underline{sf}$

so as to

$$\text{minimize } \mu_z = \underline{c}_f^t \underline{f} + \underline{c}_g^t \underline{g} - \underline{c}_p^t \underline{p} \quad (\text{II-37})$$

subject to

$$\underline{B} \underline{g} = \underline{f} \quad (\text{II-15})$$

$$\underline{p} = \underline{T} \underline{g} \quad (\text{II-16})$$

$$\underline{R}_f \underline{f} + \underline{R}_g \underline{g} + \underline{R}_p \underline{p} \begin{matrix} < \\ = \\ > \end{matrix} \underline{rhs} \quad (\text{II-26})$$

$$0.0 \leq \underline{sf} \leq 1.0 \quad (\text{II-28})$$

$$\underline{f}, \underline{g}, \underline{p} \geq 0.0 \quad (\text{II-39})$$

The problem is stochastic because some of the entries in the matrices  $\underline{B}$  and  $\underline{T}$  are random variables. There are few methods available for handling stochastic optimization subject to inequality constraints, even for linear problems (24). The difficulty lies in the selection of an optimal strategy which will remain feasible for all possible constraint sets.

The common industrial approach, when there is uncertainty about system performance, is to provide

slack (or "fat") so that the objectives for the system can be met in spite of unexpected system behavior (25). In terms of the decision problem, the "fat" ensures that a strategy which satisfies the deterministic model constraints will be feasible for the process whatever the actual values of the uncertain parameters.

Chance-constrained programming, developed by Charnes and Cooper (26), is a generalized approach to stochastic programming which permits each inequality constraint to be violated with some preset probability. The chance-constrained formulation admits no general solution procedure for problems with more than one random variable per constraint, even when those constraints are linear (27).

Another approach is to assign costs for constraint violations and minimize the process cost function plus constraint violation costs. When the uncertainties are in the constraint coefficients, this formulation is difficult to solve (again, a solution can be found only for special cases), and the optimal solution found is dependent on the penalties assigned for constraint violations (18).

In the absence of an acceptable analytical technique, when the random elements are important,

either the unmanageable aspects of the constraints are ignored, or analytical techniques are abandoned, and replaced by simulation of alternatives. Neither approach guarantees an optimal solution to the stochastic decision problem, but information about the effect of uncertainty on the choice of strategy is generated, facilitating the selection of an operating strategy which could be better, and certainly is not worse, than the strategy selected on the basis of a deterministic analysis alone.

The simulation of alternatives may be impractical for the stochastic process optimization problems because there are infinitely many alternatives, and, even if only a few are selected, simulation would require an unwarranted amount of computational effort.

The best available approach is to arrive at some compromise optimization model which is amenable to analysis but retains as much of the uncertain character of the problem as possible. If the stochastic decision problem is expressed in the reduced form (i.e. with dependent variables eliminated from the objective function), the repercussions of uncertainty are more obvious. Because the transformation equations (II-15) and (II-16) express  $\underline{f}$  and  $\underline{p}$  as functions of  $\underline{g}$

it is convenient to treat  $\underline{g}$  as a decision vector rather than  $\underline{f}$ , and

$$\underline{\mu}_g = \underline{g} \quad (\text{II-38})$$

By taking expected values on both sides of (II-15) and (II-16),

$$\underline{\mu}_f = E(\underline{B} \underline{g}) = E(\underline{B}) \underline{g} \quad (\text{II-39})$$

$$\underline{\mu}_p = E(\underline{T} \underline{g}) = E(\underline{T}) \underline{g} \quad (\text{II-40})$$

where the notation  $E(\cdot)$  denotes an expected value then, eliminating  $\underline{\mu}_f$ ,  $\underline{\mu}_p$ ,  $\underline{f}$  and  $\underline{p}$  using (II-39), (II-40), (II-15) and (II-16), the reduced stochastic programming problem can be written

find  $\underline{g}$ ,  $\underline{sf}$

so as to

$$\text{minimize } \mu_z = \left[ \underline{c}_f^t E(\underline{B}) + \underline{c}_g^t - \underline{c}_p^t E(\underline{T}) \right] \underline{g} \quad (\text{II-41})$$

subject to

$$\left[ \underline{R}_f \underline{B} + \underline{R}_g + \underline{R}_p \underline{T} \right] \underline{g} \begin{matrix} < \\ = \\ > \end{matrix} \underline{rhs} \quad (\text{II-42})$$

$$0.0 \leq \underline{sf} \leq 1.0 \quad (\text{II-28})$$

$$\underline{g} \geq 0.0 \quad (\text{II-29})$$

Because  $\underline{B}$  and  $\underline{T}$  have some random elements it is difficult to satisfy the constraints (II-42), particularly the equality constraints. These constraints cannot be ignored completely; without them  $\underline{g}$  is unbounded and the solution is trivial. One form of the bounds defined by the constraints (II-42) can be retained if the decision maker is willing to modify his restrictions so that only the expected values of the system flow variables need satisfy those constraints. With this modification, the stochastic decision problem becomes

find  $\underline{g}, \underline{sf}$

so as to

$$\text{minimize} \quad \mu_z = \left[ \underline{c}_f^t E(\underline{B}) + \underline{c}_g^t - \underline{c}_p^t E(\underline{T}) \right] \underline{g} \quad (\text{II-48})$$

subject to

$$\left[ \underline{R}_f E(\underline{B}) + \underline{R}_g + \underline{R}_p E(\underline{T}) \right] \underline{g} \begin{matrix} < \\ = \\ > \end{matrix} \underline{rhs} \quad (\text{II-43})$$

$$0.0 \leq \underline{sf} \leq 1.0 \quad (\text{II-28})$$

$$\underline{g} \geq 0.0 \quad (\text{II-29})$$

Recalling that the expected value of a matrix is the matrix of the expected values of its elements, it can be seen that the modified stochastic decision problem is identical in form to the deterministic decision problem. If the nominal values assigned uncertain parameters correspond to the expected values of the uncertain parameters, the decision problems are identical and a solution has already been obtained. If not, (for example, when the nominal values correspond to modes of parameters), the problem is easily solved by methods already discussed for the deterministic decision problem.

#### H. The "Optimal" Policy

Though the stochastic decision problem has proved to be intractable, an acceptable solution - the optimal solution to the modified problem just discussed - can be found. The next step is to interpret that solution and establish an operating strategy for the processing system.

The standard procedure would be to fix the controllable system variables at the levels indicated by the optimal solution to the modified stochastic decision problem. Such a strategy,  $S_d$ , could violate the process restrictions (II-26) if the model parameters had other than their expected values. In that case, the strategy would not be theoretically feasible though, in practice, it might well be acceptable because of "over-design" or "fat" in the process units.

An alternate procedure is to formulate an operating strategy  $S_s$  in terms of a set of simple guidelines for step-by-step determination of decision variables once process parameters are known. The guidelines attempt to reproduce the essential characteristics of the optimal solution to the modified problem while avoiding a rigid specification of decision variables. Flow rates which are at their bounds in the optimal solution should be kept there if possible. Split factors should have their optimal solution value. In practice, the guidelines are easily implemented and the resulting operating conditions do not violate process restrictions.

The strategy  $S_s$  has several advantages over a simple specification of system variables. If the

guidelines are properly defined, the strategy is always feasible, though not necessarily optimal. Because it allows for variation in system parameters, it is more versatile, and intuitively more appropriate for system operation in the face of uncertainty. Though it has not been shown here it should be possible to approximate more closely the optimal strategy for the stochastic problem, given skillfully defined guidelines. For these reasons, the strategy  $S_s$  is a more satisfactory strategy for system operation in the face of uncertainty and, for the purposes of the limited analysis being considered here, is the optimal policy.

#### J. Cost of Uncertainty

The preceding analysis yielded a strategy  $S_s$ , not necessarily optimal, for the operation of the processing system in the face of uncertainty. The objective function value  $z_s$  associated with the strategy  $S_s$  is a random variable, dependent on the uncertain value of critical system parameters. For a given set of critical system parameters, the lower limit on  $z_s$  is  $z_c$ , the value of the objective function associated with the optimal operating strategy  $S_c$  for the processing system when there is no uncertainty.  $S_c$  and  $z_c$  are just the optimal operating strategy and the minimum of

the objective function value for the deterministic decision problem when the model parameters are known with certainty. Like  $z_s$ ,  $z_c$  is a random variable.

The purpose of the present analysis is to determine the value of obtaining complete information about the critical parameters - the maximum value of improving the strategy for system operation. This value, the cost of uncertainty, is the difference  $z_s - z_c$ , a random variable; until the values of the critical parameters are known it cannot be computed. Without additional information, the best indication of the value of complete information is the expected cost of uncertainty, defined by

$$E(z_s - z_c) = \mu_{zs} - \mu_{zc} \quad (\text{II-44})$$

where  $\mu_{zs}$  and  $\mu_{zc}$  are expected values

of  $z_s$  and  $z_c$  respectively.

Neither parameter can be calculated directly. However, Monte Carlo simulation (28, 29) can be used to obtain estimates. The general procedure is to sample repetitively from the distributions of the critical

parameters, using a random number generator to generate random sets of parameters. For each set,  $z_s$  and  $z_c$  are calculated. The arithmetic means of the resulting random samples of  $z_s$  and  $z_c$  are the statistics used to estimate  $\mu_{z_s}$  and  $\mu_{z_c}$ . If  $N$  samples were taken, the mean values,

$\bar{z}_s$  and  $\bar{z}_c$  are given by

$$\bar{z}_s = \frac{1}{N} \sum_{i=1}^N z_s \{i\} \quad (\text{II-45})$$

$$\bar{z}_c = \frac{1}{N} \sum_{i=1}^N z_c \{i\} \quad (\text{II-46})$$

$$\text{and } M(z_s - z_c) = z_s - z_c \quad (\text{II-47})$$

where the notation  $M(\cdot)$  indicates the

arithmetic mean of the contents of the brackets.

When using Monte Carlo methods for comparative simulation, Hammersley and Handscomb (29) suggested that the use of the same random numbers in making two unbiased estimates, (e.g.  $\bar{z}_s$  and  $\bar{z}_c$ ) results in greater precision for the estimated difference.

The number of samples,  $N$ , is chosen so that the variance of the sample mean falls within specified limits, enabling a control on the accuracy of the estimate. Details of the calculation appear in Appendix A, and are based on the work of Shreider (28), and Hadley (30).

### III. AN APPLICATION

#### POLYMER CORPORATION'S BUTADIENE AREA

##### A. The Process

The approach to process optimization presented in the preceding chapter has been used in a study of a butadiene process similar to that found in Polymer Corporation's Butadiene Area. Typical data on costs and process characteristics, supplied by Polymer Corporation, have been modified to preserve confidentiality but remain representative of butadiene plant operation in the early 1960's.

A flowchart of the butadiene process studied here appears in figure 1; the symbols used are explained in table 1. The process is relatively complicated, consisting of 19 interconnected units, and involving 4 principle components in the process stream: normal butylene, isobutylene, butane and butadiene. Units 1 to 10 are true process units while units 11 to 19 are simple stream splitters. There are 7 external feed streams,  $pr(i,1)$  to  $pr(i,6)$  and  $fx(8)$  to  $fx(11)$ .

The process splits naturally into two sections, each producing one of the two main products of the butadiene area - butadiene and butyl rubber. Units

TABLE I  
 Explanation of Symbols Used in Figure 1  
 Units

| Unit No. | Symbol | Function                        |
|----------|--------|---------------------------------|

| fx(11)  | Overhead i-butylene from BUTYL     |

2 - 7 form the butadiene section; units 8 - 10 form the butyl rubber section. Unit 1 splits the main process feed into the feed streams appropriate to each section. The charge to unit 1,  $fx(1)$  plus recycle, is predominantly n-butylene, butane and i-butylene. Most of the i-butylene is removed for butyl rubber production while the remaining stream, rich in n-butylene, goes to the butadiene section.

The first unit in the butadiene section, unit 2, concentrates the n-butylene stream by removing most of the butane as product  $pr(i,1)$ . The concentrated n-butylene stream is then fed to unit 3 with the addition of a concentrated n-butylene feed stream,  $fx(2)$ , and process recycle. There the butylene is dehydrogenated by catalytic cracking to produce butadiene. Unit 4 removes the light and heavy products of the reaction by fractionation as product  $pr(i,2)$ . Butadiene and n-butylene may be added prior to unit 4 from feed streams  $fx(3)$  and  $fx(4)$ .

The process stream, now composed mainly of butadiene and n-butylene, is split at unit 11 and goes to either unit 5 or units 6 and 7 for butadiene extraction. There is the option of adding concentrated butadiene,  $fx(5)$ , at unit 5; dilute

butadiene,  $fx(6)$ , at unit 6; and concentrated butadiene,  $fx(7)$ , at unit 7. Unit 5 removes concentrated butadiene as product  $pr(i,3)$ , with the remaining butylene rich stream being recycled to units 1, 2, or 3 via stream splitters 12 and 13. Units 6 and 7 successively concentrate the process stream, producing concentrated butadiene as  $pr(i,4)$  from unit 7, and recycling n-butylene to units 1 or 3 via stream splitters 14 and 15.

In practice, the process stream to the butyl rubber section is almost pure i-butylene. Unit 8 concentrates the i-butylene feed from unit 1, producing product  $pr(i,5)$ . Unit 9 further prepares the process stream for processing in unit 10, recycling a portion of the stream to unit 1. Unit 10 polymerizes the isobutylene, producing butyl rubber as product  $pr(i,6)$  and recycling the remainder of the process stream to unit 1. Isobutylene may be removed from the process stream for in-plant use via stream splitters 16, 18 and 19 as products  $fx(8)$ ,  $fx(10)$  and  $fx(11)$ , or for sale via stream splitter 17 as product  $fx(9)$ .

## B. The Optimization Model

### 1. Further Development

The matrix equations which constitute the optimization model are the system model transformation equations:

$$\underline{B} \underline{g} = \underline{f} \quad (\text{II-15})$$

$$\underline{p} = \underline{T} \underline{g} \quad (\text{II-16})$$

the restrictions:

$$\underline{R_f} \underline{f} + \underline{R_g} \underline{g} + \underline{R_p} \underline{p} \begin{matrix} < \\ = \\ > \end{matrix} \underline{rhs} \quad (\text{II-26})$$

$$0.0 \leq \underline{sf} \leq 1.0 \quad (\text{II-28})$$

$$\underline{f}, \underline{p}, \underline{g} \geq 0.0 \quad (\text{II-29})$$

and the objective function:

$$\text{minimize } z = \underline{c_f}^t \underline{f} + \underline{c_g}^t \underline{g} - \underline{c_p}^t \underline{p} \quad (\text{II-30})$$

The cost function does not include fixed costs since these do not affect a decision on process operating conditions.

For this process, the compositions of the external feed streams are constant, resulting in the constraint

$$\underline{f} = \underline{f_t} \underline{Y} \quad (\text{II-1})$$

where

$f_t(k)$  = total external feed to unit  $k$

$y(i,k)$  = mass fraction of component  $i$  in  
the total external feed to unit  $k$

$$\underline{f_t} = \begin{bmatrix} f_t(1) \\ f_t(2) \\ \cdot \\ \cdot \\ f_t(n) \end{bmatrix}$$

$$\underline{Y} = \begin{bmatrix} Y_1 & Y_2 & \cdot & \cdot & \cdot & \cdot & Y_m \end{bmatrix}$$

$$\underline{y}_i = \begin{bmatrix} y(i,1) \\ y(i,2) \\ \vdots \\ y(i,m) \end{bmatrix}$$

Using (III-1),  $\underline{f}$  can be eliminated from the optimization model. The equations (II-15), (II-26) and (II-29) become

$$\underline{B} \underline{g} = \underline{f_t} \underline{y} \quad (\text{III-2})$$

$$\underline{R_{ft}} \underline{f_t} + \underline{R_g} \underline{g} + \underline{R_p} \underline{p} = \underline{rhs} \quad (\text{III-3})$$

$$\underline{f_t}, \underline{p}, \underline{g} \geq 0.0 \quad (\text{III-4})$$

and the objective function can be written

$$\text{minimize } z = \underline{c_{ft}^t} \underline{f_t} + \underline{c_g^t} \underline{g} - \underline{c_p^t} \underline{p} \quad (\text{II-5})$$

$\underline{R_{ft}}$  and  $\underline{c_{ft}^t}$  are the constraint and cost coefficients of the external feed  $\underline{f}$ , appropriately redefined in terms of  $\underline{f_t}$ . Equations (II-16), (II-28) and (III-2) through (III-5)

make up a general optimization model.

One other modification to the model is desirable. The model as developed, allows for precisely one feed and one product stream per unit. In practice, as can be seen from the flowchart, figure 1, this need not be the case. A more efficient notation can be developed as follows. Define:

$fx(j) = j^{\text{th}}$  external feed stream.

$y^*(i,j,k)$  = mass fraction of component  $i$   
in the  $j^{\text{th}}$  external feed stream,  $fx(j)$ ,  
a stream which goes to unit  $k$ .

$y^*(i,j,kk) = 0.0 \quad kk=1,\dots,n \quad kk \neq k$

$pr(i,j)$  = mass flow of component  $i$  in the  $j^{\text{th}}$   
external product stream.

$d^*(i,j,k)$  = mass fraction of the total flow of  
component  $i$  to unit  $k$  which leaves the  
system as the  $j^{\text{th}}$  product  $pr(i,j)$ .

$d^*(i,j,kk) = 0.0 \quad kk=1,\dots,n \quad kk \neq k$

nf = number of external feed streams

np = number of external product streams

Then

$$\underline{f_x} = \begin{bmatrix} f_x(1) \\ f_x(2) \\ \cdot \\ \cdot \\ f_x(nf) \end{bmatrix} \quad (\text{II-6})$$

$$\underline{Y^*} = \begin{bmatrix} \underline{Y_1^*} & \cdot & \cdot & \cdot & \underline{Y_i^*} & \cdot & \cdot & \cdot & \underline{Y_m^*} \end{bmatrix} \quad (\text{II-7})$$

where

$\underline{Y_i^*}$  is an (nf x n) matrix

with elements  $y_{jk}^* = y^*(i,j,k)$

$$\underline{pr} = \begin{bmatrix} pr(1,1) \\ pr(1,2) \\ \cdot \\ \cdot \\ pr(m,1) \\ pr(m,2) \\ \cdot \\ \cdot \\ pr(m,np) \end{bmatrix} \quad (\text{II-8})$$

$$\underline{D}^* = \begin{bmatrix} \underline{D}_1^* & & & \\ & \underline{D}_2^* & & \\ & & \cdot & \\ & & & \cdot \\ & & & & \underline{D}_m^* \end{bmatrix} \tag{II-9}$$

$\underline{D}_i^*$  is an (np x n) matrix

with elements  $d_{jk}^* = d^*(i,j,k)$

The optimization model, written in terms of these variables, consists of the transformation equations:

$$\underline{B} \underline{g} = \underline{f_x} \underline{Y}^* \tag{III-10}$$

$$\underline{pr} = \underline{T}^* \underline{g} \tag{III-11}$$

where

$$\underline{T}^* = \underline{D}^* + \underline{D}^* \underline{S}$$

the restrictions:

$$\frac{R_{fx} \underline{fx}}{\underline{}} + \frac{R_g \underline{g}}{\underline{}} + \frac{R_{pr} \underline{pr}}{\underline{}} = \frac{\underline{rhs}}{\underline{}} \quad (\text{III-12})$$

$$0.0 \leq \underline{sf} \leq 1.0 \quad (\text{II-28})$$

$$\underline{fx}, \underline{g}, \underline{pr} \geq 0.0 \quad (\text{III-13})$$

and the objective function:

$$\text{minimize } z = \underline{c}_{fx}^t \underline{fx} + \underline{c}_g^t \underline{g} - \underline{c}_{pr}^t \underline{pr} \quad (\text{III-14})$$

There is no change in the form of the optimization model; the theory developed in the previous chapter remains applicable.

## 2. The Specific Model

The specific model has been developed and tested in the form just discussed. The process can be represented by 19 units, 9 of which are stream splitters, characterized by variable split factors. The streams passing through units 16 to 19 contain only one component, isobutylene. Consequently, those units can be eliminated from the formulation provided that their product streams,  $fx(8)$  to  $fx(11)$  are regarded as negative feed streams to units 8, 9, and 10. For this

model,  $fx(8)$  to  $fx(11)$  appear as external feed streams with negative compositions.

The data for the model, based on that provided by Polymer Corporation, follows. There are four components, designated as follows:

| <u>i</u> | <u>component</u> |
|----------|------------------|
| 1        | n-butylene       |
| 2        | i-butylene       |
| 3        | butane           |
| 4        | butadiene        |

The integer parameters are:

|                               |          |
|-------------------------------|----------|
| no. of components             | $m = 4$  |
| no. of units                  | $n = 15$ |
| no. of external feed streams  | $nf=11$  |
| no. of product streams        | $np=6$   |
| no. of variable split factors | $ns=5$   |

Pertinent data for the matrices  $\underline{B}$ ,  $\underline{Y}^*$ , and  $\underline{T}^*$ , the  $a(i,j,k)$ ,  $y^*(i,j,k)$  and  $d^*(i,j,k)$ , are given in tables 2 - 4. The matrix of reaction conversion factors  $\underline{S}$  has only two nonzero entries. They describe the conversion of n-butylene to butadiene in unit 3. The nominal values are:

$$s(1,1,3) = -0.4$$

$$s(4,1,3) = 0.4$$

With these data, the transformation equations are defined.

The constraints which make up the restrictions (III-12) are the feedstock availability limits:

$$fx(1) \leq 0.96 \quad (III-15)$$

$$fx(2) \leq 0.105 \quad (III-16)$$

$$fx(3) \leq 0.027 \quad (III-17)$$

$$fx(4) + fx(5) \leq 0.014 \quad (III-18)$$

$$fx(6) \leq 0.038 \quad (III-19)$$

$$fx(7) \leq 0.045 \quad (III-20)$$

unit capacity constraints:

$$\sum_{i=1}^m g(i,2) \leq 1.05 \quad (III-21)$$

$$g(2,1) \leq 0.23 \quad (III-22)$$

$$g(1,2) \leq 0.66 \quad (III-23)$$

$$g(1,3) \leq 1.15 \quad (III-24)$$

$$g(4,5) \leq 0.26 \quad (III-25)$$

$$g(4,6) \leq 0.26 \quad (III-26)$$

$$g(2,10) \leq 0.14 \quad (III-27)$$

product requirements:

$$p(4,3) + p(4,4) \leq 0.06 \quad (III-28)$$

$$p(4,3) + p(4,4) \geq 0.34 \quad (\text{III-29})$$

and model validity requirements:

$$fx(8) - a(2,8,9) g(2,8) \leq 0.0 \quad (\text{III-30})$$

$$fx(9) - a(2,9,1) g(2,9) \leq 0.0 \quad (\text{III-31})$$

$$fx(10) - a(2,9,10) g(2,9) \leq 0.0 \quad (\text{III-32})$$

$$fx(11) - a(2,10,1) g(2,10) \leq 0.0 \quad (\text{III-33})$$

The constraints (III-30) to (III-33) ensure that the material balance on units 16 to 19 is not violated.

Constraints (II-28) and (III-13) complete the restrictions on system variables.

The objective function has the form of (III-14) with coefficients as defined in tables 5-7.

The decision variables for the optimization model will be the external feed streams  $fx(1)$  to  $fx(11)$  and the split factors for units 11 to 15. They correspond to the recovery factors  $a(i,11,5)$ ,  $a(i,12,3)$ ,  $a(i,13,1)$ ,  $a(i,14,1)$  and  $a(i,15,1)$ ; initial values for these factors are given in table 3.

All flow rates are in millions of pounds per day, and costs are in tenths of a dollar per pound. Consequently, the objective function is in hundred thousands of dollars per day. It should be emphasized that the objective function value has no

a (i,15,1) = 0.05

physical significance because fixed costs are not included in the analysis. It is only useful for comparison.

### 3. Verification

For testing purposes, linear programming was used to find optimal solutions to the specific optimization model for the butadiene process. The split factors were treated as fixed at their initial values as presented in table 2.

A Fortran program was written to generate both the general and reduced forms of the optimization model in a form suitable for input to MPS/360, IBM's mathematical programming system (30). MPS/360 was used to obtain an optimal solution to the linear programming problem, and their parametric procedures were helpful in pinpointing data inconsistencies.

Several data errors and model errors were corrected resulting in the model just presented. The solution to the linear programming problem places the system variables at levels very similar to the original plant operating conditions. It provides an excellent reference point for comparison with the nonlinear optimization procedures to be discussed in later sections. The solution appears in table 8.

The Fortran programs for model generation from data and MPS/360 programs for the linear programming solutions appear in Appendix B along with program documentation. A separate subroutine was written to handle model data input. Printouts, documentation and input data appear in Appendix C. This subroutine was used for model data input to all of the programs used in the course of the butadiene area optimization.

### C. The Deterministic Decision

The deterministic decision problem can be defined symbolically as the following nonlinear programming problem

Find  $\underline{f}$ ,  $\underline{sf}$

so as to

$$\text{minimize } z = \underline{c}_{fx}^t \underline{fx} + \underline{c}_g^t \underline{g} + \underline{c}_{pr}^t \underline{pr} \quad (\text{III-14})$$

Subject to:

$$\underline{B} \underline{g} = \underline{fx} \underline{Y}^* \quad (\text{III-10})$$

$$\underline{pr} = \underline{T}^* \underline{g} \quad (\text{III-11})$$

$$\underline{R}_{fx} \underline{fx} + \underline{R}_g \underline{g} + \underline{R}_{pr} \underline{pr} \begin{matrix} < \\ = \\ > \end{matrix} \underline{rhs} \quad (\text{III-12})$$

$$0.0 \leq \underline{sf} \leq 1.0 \quad (\text{III-28})$$

$$\underline{fx}, \underline{g}, \underline{pr} \geq 0.0 \quad (\text{III-13})$$

Since there are only 5 variable split factors the hill-climbing technique suggested in Chapter II, section D, can be employed to solve the problem. The pattern search method of Hooke and Jeeves (19), as described by Wilde and Beightler (20), is used for the nonlinear search. At each trial, a set of values for the  $\underline{sf}$  is generated and used to define a corresponding linear programming problem which is solved to determine optimal external feed rates for that trial. Dantzig's two-phase simplex algorithm (25) can be used to solve the linear programming problem.

The form of the nonlinear programming problem used for the pattern search solution can be described symbolically as:

find  $\underline{sf}$

so as to

$$\text{minimize } z = \underline{c}_{fx}^t \underline{fx} + \underline{c}_g^t \underline{B}^{-1} \underline{fx} \underline{y}^* - \underline{c}_{pr}^t \underline{T}^* \underline{B}^{-1} \underline{fx} \underline{y}^*$$

(III-34)

subject to:

$$0.0 \leq \underline{s_f} \leq 1.0 \quad (\text{III-28})$$

$\underline{f_x} = \underline{f_{x_s}}$  chosen so as to

$$\text{minimize } z_s = \underline{c_{f_x}^t} \underline{f_{x_s}} + \underline{c_g} \underline{B}^{-1} \underline{f_{x_s}} \underline{Y^*} - \underline{c_{pr}^t} \underline{T^*} \underline{B}^{-1} \underline{f_{x_s}} \underline{Y^*} \quad (\text{III-34})$$

subject to:

$$\underline{R_{f_x}} \underline{f_{x_s}} + \underline{R_g} \underline{B}^{-1} \underline{f_{x_s}} \underline{Y^*} - \underline{R_{pr}} \underline{T^*} \underline{B}^{-1} \underline{f_{x_s}} \underline{Y^*} \begin{matrix} < \\ = \\ > \end{matrix} \underline{rhs} \quad (\text{III-35})$$

$$\underline{f_{x_s}} \geq 0.0 \quad (\text{III-13})$$

Note that the reduced form of the problem has been developed, as in chapter 2, by using the transformation equations (III-10) and (III-11) to eliminate the variables  $\underline{pr}$  and  $\underline{g}$ .

The deterministic decision problem was solved in the manner proposed above. The recovery factors, product recovery factors and reaction conversion factors were assigned their nominal values. Initial values for the split factors were the nominal values given in table 3. No computational difficulties were encountered.

The solution to the deterministic problem appears in table 9. As can be seen, the use of nonlinear programming to determine optimal split

factors has brought about a substantial improvement in the objective function value, close to \$6,000 dollars per day. The solution was compared with available information on the operation of the existing system to confirm that the results are realistic. No inconsistencies were observed.

A check was made on the location of the optimum by solving the nonlinear programming problem for several sets of initial split factor values. No alternate optima were found. Initial conditions and optimization results for these cases appear in Appendix F.

The program used to solve the nonlinear programming problem can be conveniently divided into four sections, each of which has been dealt with in a separate appendix. Printouts, documentation and computational details are included for each. The mainline program for the pattern search solution and the pattern search algorithm appear in Appendix F. Model data input routines and formats are covered in Appendix C. Appendix E deals with the fortran programs used to generate the reduced form of the optimization model, given completely specified technology matrices. Finally, Appendix D is concerned with the simple Fortran

subroutines written to set up the optimization model in the form required by Dantzig's two-phase simplex algorithm (25), to solve the linear programming problem, and to organize and printout the results and error messages. The material in Appendices C, D, and E is presented separately because these programs were used repeatedly throughout the analysis.

#### D. Sensitivity Analysis

##### 1. Model Parameters

A sensitivity analysis was carried out on the system model parameters,  $a(i,j,k)$ ,  $d^*(i,j,k)$  and  $s(i,q,k)$  to determine which are critical to the system representation. Most of the parameters are coupled, either by the equivalent of (II-17)

$$\sum_{kk=1}^{np} d^*(i,kk,j) + \sum_{k=1}^n a(i,j,k) \leq 1.0 \quad (\text{III-36})$$

or by

$$\sum_{i=1}^m s(i,q,j) \leq 0.0 \quad (\text{II-20})$$

These relations can be written as equalities by adding a term for losses.

$$\sum_{kk=1}^{np} d^*(i, kk, j) + \sum_{k=1}^n a(i, j, k) + \text{losses} = 1.0 \quad (\text{III-37})$$

$$\sum_{i=1}^m s(i, q, j) + \text{losses} = 0.0 \quad (\text{III-38})$$

In general, losses are small. If they are treated as constant, then equations (III-37) and (III-38) can be used to define the joint relationships between coupled parameters. The parameter couplings defined by equations (III-37) and (III-38) are easily identified. Unit 4 is a special case. For this unit, the relationships

$$a(i, 4, 11) = a(q, 4, 11) \quad i=1, \dots, m \quad (\text{III-39})$$

$$d^*(i, 2, 4) = d^*(q, 2, 4) \quad i=1, \dots, m \quad (\text{III-40})$$

also hold and must be accounted for in the sensitivity analysis.

Each parameter has been assigned an interval of uncertainty, symmetrical about the nominal value, which reflects initial information about the range of the parameter. Those parameters with an interval size of 0.0 are considered to be known with certainty.

The parameters, their nominal values and the assigned interval size appear in table 10. Parameter couplings are also indicated there.

The sensitivity analysis is carried out by perturbing a single base parameter, adjusting any coupled parameters according to the appropriate relationship, and observing the effect on objective function value. For each perturbation, the split factors are held constant at their optimal level and the optimal solution to the resulting linear programming problem is found. This is the objective function value used for comparison with the reference value, the value of the optimal solution to the deterministic problem. An attempt to compare objective function values without determining new optimal feed rates for the perturbed problem would be meaningless; the optimal strategy for the deterministic problem will not always be feasible for the perturbed problem.

The computer summary of sensitivity analysis results appears in Table 11. Each perturbation is identified only by a perturbation sequence number. This sequence number is correlated with the base parameter perturbed, the amount of the perturbation, and the total objective function value change over the perturbation interval in Table 12.

For this analysis, those parameters whose perturbation caused a single variation in objective function value greater than 4%, and a total variation

| 15,16        | a (4,5,12) | $\pm 0.025$  | 3.2            |
| 17,18        | a (1,6,7)  | $\pm 0.05$   | 0.18           |
| 19,20        | a (2,6,7)  | $\pm 0.05$   | 0.12           |
| 21,22        | a (4,6,7)  | $\pm 0.025$  | 1.1            |
| 23,24        | a (4,7,15) | $\pm 0.025$  | 1.1            |
| 25,26        | a (2,8,9)  | $\pm 0.05$   | 7.8            |
| 27,28        | a (2,9,1)  | $\pm 0.05$   | 6.3            |
| 29,30        | a (2,10,1) | $\pm 0.05$   | 13.5           |
| 31,32        | s (1,1,3)  | $\pm 0.075$  | 3.2            |

greater than 6%, were identified as critical parameters. From tables 11 and 12, in order of sensitivity, the critical parameters are:

| Parameter | Coupled | Parameter  |
|-----------|---------|------------|
| a(2,10,1) |         | d*(2,6,10) |
| a(2,1,2)  |         | a(2,1,8)   |
| a(2,8,9)  |         | d*(2,5,8)  |
| a(i,4,11) |         | d*(i,2,4)  |
| a(4,3,4)  |         |            |
| a(2,9,1)  |         | a(2,9,10)  |

On the basis of this sensitivity analysis it is assumed that uncertainty in the remaining non-critical parameters has a negligible effect on the decision problem. They are treated as if they were known, with certainty, to have their nominal values.

As Demski (22) has pointed out, the set of critical parameters just identified is not necessarily stable over changes in model parameters, model structure or process operating conditions. Their applicability to the existing process is dependent on the realism of the model representation.

Printouts, documentation and computational details of programs written to perform the sensitivity analysis appear in Appendix G.

## 2. Split Factors

A sensitivity analysis was carried out to identify those split factors which have a critical effect on objective function value. It was accomplished in two stages.

In the first stage, each variable split factor was perturbed in turn about its optimal level, the optimal solution to the corresponding linear programming problem was found, and the change in objective function value observed. The computer summary of the results appears in Table 13. The perturbation sequence number appearing on the computer printout, Table 13, is correlated with the split factor perturbation and the split factor's optimal value in Table 14. Split factor  $a(i,13,1)$  was not perturbed because unit 13 is not used in the optimal solution to the deterministic problem.

From Table 13, only split factors  $a(i,11,5)$  and  $a(i,12,3)$  are noticeably sensitive.

The second stage, termed the range analysis, is performed to determine whether or not there could be an appreciable change in the optimal values of the sensitive split factors due to the uncertainty in the critical parameters. Each critical parameter was

perturbed in turn as in the parameter sensitivity analysis. For each perturbation, the non-sensitive split factors were held constant at their optimal level, and the solution to the corresponding nonlinear programming problem found. The computer summary of results appears in Table 15. The perturbation sequence number is correlated with the critical parameter perturbation in Table 16.

As can be seen from Table 15, no appreciable variation in the optimal value of the sensitive split factors was observed. Therefore, the split factors may reasonably be treated as constants, fixed at their optimal value.

As Demski (22) pointed out, these results are valid only so long as no substantial changes are made in model parameters structure; or operating conditions; they need not be applicable to the existing process if the model's representation is poor.

Printouts, documentation and computational details of programs written to perform the sensitivity analysis appear in Appendix G.

## E. The Probabilistic Phase

### 1. Encoding Uncertainty

Each of the model parameters identified as uncertain is assigned a probability distribution in accordance with the state of knowledge about the parameter. In this case the probability distributions are subjective, assigned on the basis of opinion analysis. The distributions are assumed to be independent and normal with parameters as detailed in Table 17.

The expected value of each distribution is identical to the nominal value assigned to the critical parameter. The probability that the critical parameter value will lie outside the interval assigned for the sensitivity analysis can be calculated from the definition of the normal distribution (30).

That is

$$p(|\beta_i - \mu_{\beta_i}| > \delta_{\beta_i}) = 2 (1 - \Phi(\delta_{\beta_i} / \sigma_{\beta_i})) \quad (\text{III-41})$$

where  $\beta_i = i^{\text{th}}$  critical parameter

TABLE 17

Subjective Probability Distribution Parameters

Normal Distribution

$\mu_{\beta}$  = expected value

$\sigma_{\beta}^2$  = variance

| Symbol    | Parameter  | $\mu_{\beta}$ | $\sigma_{\beta}^2$ |
|-----------|------------|---------------|--------------------|
| $\beta_1$ | d*(2,6,10) | 0.85          | 0.0004             |
| $\beta_2$ | a(2,1,8)   | 0.85          | 0.0004             |
| $\beta_3$ | a(2,8,9)   | 0.8           | 0.0004             |
| $\beta_4$ | a(i,4,11)  | 0.95          | 0.0001             |
| $\beta_5$ | a(4,3,4)   | 0.9           | 0.0004             |
| $\beta_6$ | a(2,9,1)   | 0.1           | 0.0004             |

$\mu_{\beta_i}$  = expected value,  $\beta_i$

$2\delta_{\beta_i}$  =  $\beta_i$  interval size

$\sigma_{\beta_i}^2$  = variance,  $\beta_i$

$\Phi$  = standardized cumulative normal  
probability distribution

$p(\epsilon)$  = probability of the event  $\epsilon$

For all critical parameters, that probability is 0.0124. Because the normal distribution is unbounded there is a finite probability that the critical parameter value,  $\beta_i$  will violate one of the constraints (II-18) and (II-19). It is indistinguishable from 0.0000 and hence negligible. Details of these calculations appear in Appendix A.

The subjective probability distributions have been shown to be consistent with the information available for the sensitivity analysis.

## 2. The Optimal Policy

Because the expected values of the critical parameter distributions are identical to their nominal values, the solution to the modified stochastic

problem is identical to the solution to the deterministic problem, Table 9. An optimal policy, expressed in terms of a set of guidelines for process operation, can be formulated on the basis of that solution.

The following characteristics of the optimal solution to the deterministic problem are noted:

$$fx(6) = 0.038 \quad \text{upper limit} \quad - \quad (III-19)$$

$$fx(9) = 0.01556 \quad \text{upper limit} \quad - \quad (III-31)$$

$$fx(3), fx(4), fx(5), fx(7) = 0.0$$

$$fx(8), fx(10), fx(11) = 0.0$$

$$g(2,10) \quad \text{upper limit} \quad - \quad (III-27)$$

$$p(4,3) + p(4,4) \quad \text{upper limit} \quad - \quad (III-29)$$

$$g(2,1) = 0.22876 \quad \text{close to capacity} \quad - \quad (III-22)$$

$$g(4,5) = 0.25985 \quad \text{close to capacity} \quad - \quad (III-25)$$

A set of guidelines formulated on the basis of these characteristics is:

1. Use all available  $fx(9)$ .
2. Use all available  $fx(6)$ .
3. Use no  $fx(8)$ ,  $fx(10)$ ,  $fx(11)$ .
4. Use no  $fx(3)$ ,  $fx(4)$ ,  $fx(5)$ ,  $fx(7)$ .
5. Use as much  $fx(1)$  as possible.
6. Use as much  $fx(2)$  as possible.

The guidelines can be formally incorporated into an optimization model by specifying a new objective function to account for guidelines 1,5, and 6 and additional constraints ensuring adherence to guidelines 2,3, and 4. A suitable objective function would take the form:

$$\text{minimize } z_s = c_1 fx(9) + c_2 fx(1) + c_3 fx(2) \quad (\text{III-42})$$

$$c_1 < c_2 < c_3$$

Examination of the optimal solution to the deterministic problem reveals other useful information. For the butadiene process discussed here, the butyl rubber section can operate close to capacity. There is excess capacity in the butadiene section, and hence opportunity for additional profit if additional markets and additional suitable feedstock, such as  $fx(2)$ , can be found.

#### F. Expected Cost of Uncertainty

The expected cost of uncertainty is an indication of the value of obtaining complete information about the critical parameters. Monte Carlo simulation, as outlined in Chapter II, section J, was

used to obtain an unbiased estimate of the expected cost of uncertainty.

A series of independent random samples of the cost of uncertainty is generated. For the  $j^{\text{th}}$  sample, the procedure is:

1. Using normally distributed random numbers supplied by IBM's random number generator (32), an independent random,  $\beta_i \{j\}$ , is obtained from each critical parameter's probability distribution.

2. The  $j^{\text{th}}$  system model is defined using the  $\beta_i \{j\}$ . The model is linear because the split factors can be treated as fixed.

3. The objective function value  $z_s \{j\}$ , corresponding to the operating strategy formulated in terms of guidelines (section E-2) is calculated. The solution of a linear programming problem is required.

4. The objective function value  $z_c \{j\}$ , corresponding to the optimal strategy for the  $j^{\text{th}}$  system model, is calculated. The solution of the deterministic optimization problem for the  $j^{\text{th}}$  system model, a linear programming problem, is required.

5. The cost of uncertainty is  $z_s \{j\} - z_c \{j\}$ . If  $N$  samples were generated an estimate of the expected cost of uncertainty is the arithmetic mean of the random samples, that is:

$$E(z_s - z_c) \approx M(z_s - z_c) = \bar{z}_s - \bar{z}_c \quad (\text{II-47})$$

where

$$\bar{z}_s = \frac{1}{N} \sum_{i=1}^N z_s \{i\} \quad (\text{II-45})$$

$$\bar{z}_c = \frac{1}{N} \sum_{i=1}^N z_c \{i\} \quad (\text{II-46})$$

Accuracy is estimated as suggested in Appendix A.

After 200 simulations, the expected cost of uncertainty was estimated to be 130 dollars per day. With a 95% confidence level, the estimate falls within the interval  $(130 \pm 20)$  dollars per day. The standard deviation of the cost of uncertainty is about 140 dollars per day. The computer summary of results appears as Table 18.

The cost of uncertainty is somewhat lower than the sensitivity analysis on parameters would indicate. It is just 0.5% of the objective function value, while single critical parameter perturbations resulted in changes greater than 4%. It is unlikely that this is entirely a result of interaction of deviations. A more plausible explanation is that the low cost of uncertainty is an indication of the value of expressing

the optimal policy in terms of a set of guidelines.

A computer printout of sample points is included in Appendix H, table H-4. From the tabulation it can be seen that the cost of uncertainty, (the regret), is usually either negligible or on the order of 300 dollars per day. (Values less than about  $1.0 \times 10^{-7}$  in magnitude are equivalent to zero due to roundoff errors). This indicates that the strategy based on guidelines was near optimal much of the time, but failed to account for all possibilities. The operating strategy might be improved by using detailed information generated for the simulation procedure to develop a more versatile set of guidelines.

Printouts, documentation and computational details of programs written to perform the cost of uncertainty estimation appear in Appendix H.

#### IV. DISCUSSION AND CONCLUSIONS

The use of a macroscopic system model in conjunction with decision analysis techniques has been suggested as a valid approach to the problem of optimal operation of an existing processing system in the face of uncertainty.

##### A. The Butadiene Process

The butadiene process case study provided valuable insight into optimal operation of the process with a minimum of effort. Deterministic optimization of the nonlinear process model yielded a set of overall operating conditions which could reduce the marginal cost function for the process by about 6,000 dollars per day. A sensitivity analysis pinpointed those system parameters which are most critical to optimal system operation, and showed that split factors were not critical in the neighborhood of the optimum. A set of guidelines were developed which would indicate near-optimal operating conditions regardless of the exact state of the critical parameters. An estimate of the cost of uncertainty was made, showing that little could be gained by further information gathering. The cost of uncertainty was lower than would have been expected from sensitivity analysis results. This is

an indication of the effect of expressing the strategy for operation in the face of uncertainty in terms of a set of guidelines.

This information forms an excellent base for further, more detailed, optimization studies. The critical areas of the process have been identified, overall operating conditions for individual units have been specified, and any changes in unit behavior can be quickly evaluated.

#### B. General Application

The approach suggested here is expected to be generally applicable to a wide variety of process operation problems. It has the advantage of providing needed information about overall operation with relatively little effort. Hence, it provides a good framework for later suboptimization.

The system model developed is mathematically tractable and relatively easily defined though in some cases it may not be adequate. It should be most useful for large problems with extensive sections of the process classed as units; the larger units are more amenable to simple representation.

The simple sensitivity analysis for system parameters should be adequate for most applications. In large problems the number of parameters that can

reasonably be sensitized is limited. Prior knowledge of process operation should be sufficient to indicate areas most likely to be critical.

For most industrial problems, it would be unrealistic to act as if uncertainty does not exist. The definition of the optimal strategy in the face of uncertainty in terms of simple guidelines, suitable for actual process operation, holds promise. The approach is more realistic than a straight forward specification of operating conditions, and has the capability of being nearer to optimal.

The estimation of the cost of uncertainty is valuable as a quantitative indication of the additional expenditure warranted in an effort to remove uncertainty from the model. Monte Carlo simulation may appear to be unreasonably expensive for this purpose. This is not necessarily so. As few as 25 - 30 simulations may be adequate, depending on the accuracy required of the estimate.

As with most optimization methods, the major limitation lies in the fact that the results of the study are valid only for the model. They are applicable to the process only to the extent that the model is an accurate representation of process behavior.

### C. Future Work

The extension of the present work to dynamic system models would be advantageous. The theory of dynamic input-output models used in economics, has been developed (5). The only problems appear to be handling variable split factors and formulating the appropriate process model.

The extension of the analysis to account for uncertainty in the cost coefficients and constraint requirements is straight forward. Though the stochastic optimization model is more complex, the same approach can be used to handle it.

The macroscopic model could be useful in process design problems, both for evaluation of alternate configurations and determination of operating conditions. It may have some use in setting overall process unit characteristics as well. There, the emphasis would be on determining the best of possible system parameters.

| $np$              | - | no. of product streams   |
| $ns$              | - | no. of variable split factors                                      |

|                      |   |  |
|----------------------|---|--|
| $N$                  | - | no. of random samples, Monte Carlo simulation  |
| $p(i,k)$             | - | $i^{\text{th}}$ component, external product stream from unit $k$                       |
| $\underline{p}_i$    | - | external product stream vector of $i^{\text{th}}$ component, $p(i,k)$                  |
| $\underline{p}$      | - | external product stream vector of $p(i,k)$   |
| $pr(i,k)$            | - | $i^{\text{th}}$ component, $k^{\text{th}}$ external product stream                     |
| $\underline{pr}_i$   | - | external product stream vector of $i^{\text{th}}$ component, $pr(i,k)$                 |
| $\underline{pr}$     | - | external product stream vector of $pr(i,k)$  |
| $\underline{rhs}$    | - | requirements vector, restriction relations   |
| $\underline{R}_f$    | - | matrix of coefficients of $\underline{f}$ , restriction relations                      |
| $\underline{R}_{ft}$ | - | matrix of coefficients of $\underline{ft}$ , restriction relations                     |
| $\underline{R}_{fx}$ | - | matrix of coefficients of $\underline{fx}$ , restriction relations                     |
| $\underline{R}_g$    | - | matrix of coefficients of $\underline{g}$ , restriction relations                      |
| $\underline{R}_p$    | - | matrix of coefficients of $\underline{p}$ , restriction relations                      |
| $\underline{R}_{pr}$ | - | matrix of coefficients of $\underline{pr}$ , restriction relations                     |
| $s(i,q,k)$           | - | reaction conversion factor, component $i$ to component $q$ in the $k^{\text{th}}$ unit |

|                       |   |
|-----------------------|---|
| $\underline{S}_{i,q}$ | - reaction conversion factor matrix, component $i$ to component $q$             |
| $\underline{S}$       | - reaction conversion factor matrix   |
| $sf_k$                | - $k^{\text{th}}$ variable split factor   |
| $\underline{sf}$      | - vector of variable split factors  |
| $\underline{T}$       | - coefficient matrix for product stream $\underline{p}$ transformation equation |
| $\underline{T}^*$     | - coefficient matrix for product stream $\underline{pr}$                        |
| $y(i,k)$              | - mass fraction of component $i$ in $ft(k)$                                     |
| $\underline{y}_i$     | - mass fraction matrix for $i^{\text{th}}$ component, $\underline{ft}$          |
| $\underline{y}$       | - mass fraction matrix for $\underline{ft}$                                     |
| $y^*(i,j,k)$          | - mass fraction of component $i$ in $fx(k)$                                     |
| $\underline{y}_i^*$   | - mass fraction matrix for $i^{\text{th}}$ component, $\underline{fx}$          |
| $\underline{y}^*$     | - mass fraction matrix for $\underline{fx}$                                     |
| $z$                   | - objective function value  |
| $z_c$                 | - objective function value for $S_c$  |
| $z_c\{j\}$            | - $z_c$ , $j^{\text{th}}$ random sample   |
| $\bar{z}_c$           | - arithmetic mean, $z_c$ , after $N$ random samples                             |
| $z_s$                 | - objective function value for $S_s$  |
| $z_s\{j\}$            | - $z_s$ , $j^{\text{th}}$ random sample   |
| $\bar{z}_s$           | - arithmetic mean, $z_s$ , after $N$ random samples                             |
| $p(\epsilon)$         | - probability of event $\epsilon$   |
| $S_c$                 | - optimal strategy under certainty  |
| $S_D$                 | - deterministic strategy - specification of system variables                    |

|                      |   |  |
|----------------------|---|--|
| $S_s$                | - | stochastic strategy - specification of guidelines                |
| $\beta_i$            | - | $i^{\text{th}}$ critical parameter, treated as a random variable |
| $\beta_i\{j\}$       | - | $j^{\text{th}}$ random sample of $\beta_i$                       |
| $\sigma_{\beta_i}$   | - | one half interval size, $\beta_i$                                |
| $\Phi(t)$            | - | standardized cumulative normal probability distribution          |
| $\mu_{\beta_i}$      | - | expected value, $\beta_i$  |
| $\mu_z$              | - | expected value, $z$  |
| $\mu_f$              | - | expected value, $\underline{f}$                                  |
| $\mu_g$              | - | expected value, $\underline{g}$                                  |
| $\mu_p$              | - | expected value, $\underline{p}$                                  |
| $\sigma^2_{\beta_i}$ | - | variance, $\beta_i$  |

# 1. Accuracy of Monte Carlo Estimation of an Expected Value

The following discussion of the accuracy of Monte Carlo estimation of expected value is based on material appearing in the texts of Schreider (28) and Hadley (30).

The statistic used to estimate the expected value,  $E(x)$ , of the random variable,  $x$ , is the arithmetic mean  $\bar{x}$  of  $N$  independent samples  $x\{j\}$  from the probability distribution of  $x$ . The arithmetic mean is defined by

$$\bar{x} = \frac{1}{N} \sum_{i=1}^N x\{i\} \quad (A-1)$$

From the central limit theorem of probability theory, for large  $N$  the distribution of the random variable  $\bar{x}$  is approximately normal. The expected value and variance of  $\bar{x}$  are give by

$$E(\bar{x}) = E(x) = \mu_x \quad (A-2)$$

$$\sigma_{\bar{x}}^2 = \frac{\sigma_x^2}{N} \quad (A-3)$$

It is desired to specify that, with probability  $1 - \lambda$ , the estimate  $\bar{x}$  should fall within the interval  $(\mu_x \pm \delta)$ . From the definition of the normal distribution

$$p(|\bar{x} - \mu_x| > \delta) \approx \lambda = 2 \left[ 1 - \Phi \left( \frac{\delta}{\sigma_{\bar{x}}} \right) \right] \quad (\text{A-4})$$

If

$$\delta = \alpha \sigma_{\bar{x}} \quad (\text{A-5})$$

then, (A-4) can be written

$$p(|\bar{x} - \mu_x| > \delta) \approx \lambda = 2 \left[ 1 - \Phi(\alpha) \right] \quad (\text{A-6})$$

Substituting (A-3) in (A-5), the number of samples required can be estimated from

$$N = \left( \frac{\alpha \sigma_x}{\delta} \right)^2 \quad (\text{A-7})$$

Unfortunately, the parameter  $\sigma_x^2$  is not usually known; it too must be estimated in the course of the simulation. An unbiased estimate of  $\sigma_x^2$  is the standard deviation,  $s_x$ , defined by

$$s_x^2 = \frac{1}{N-1} \left[ \sum_{j=1}^N x\{j\}^2 - N\bar{x}^2 \right], \quad N > 1 \quad (\text{A-8})$$

Then, given an initial estimate of  $s_x$  from a few, say 30, samples, the number of samples required can be estimated from

$$N \approx \left[ \frac{\alpha s_x}{\delta} \right]^2 \quad (A-9)$$

where  $s_x$  has been substituted for  $\sigma_x$  in (A-7).

A more convenient procedure would be to continue sampling until the precision requirement is satisfied, that is

$$\frac{\alpha s_x}{N^{\frac{1}{2}}} \leq \delta \quad (A-10)$$

Given  $\lambda$ , the confidence level,  $\alpha$  is defined by (A-6).

Shreider suggest that  $\lambda = 0.95$ , a 95% level of confidence, is suitable which corresponds to  $\alpha = 1.96$

## 2. Calculation of $p(|\beta - \mu| > \delta)$

This calculation is based on the definition and table of the standardized cumulative normal distribution function,  $\Phi(t)$ , found in Hadley's text (30).

$$\begin{aligned}
 p(|\beta_i - \mu_{\beta_i}| > \delta_{\beta_i}) &= \Phi\left(\frac{-\delta_{\beta_i}}{\sigma_{\beta_i}}\right) + 1 - \Phi\left(\frac{\delta_{\beta_i}}{\sigma_{\beta_i}}\right) \\
 &= 2 \left[ 1 - \Phi\left(\frac{\delta_{\beta_i}}{\sigma_{\beta_i}}\right) \right] \quad (A-11)
 \end{aligned}$$

Table A-1 details the calculation for each  $\beta_i$ .

The probability that a critical parameter,  $\beta_i$ , would violate an upper or lower bound, is, in the worst case ( $\beta_1, \beta_4, \beta_5, \beta_6$ ), equivalent to

$$\begin{aligned}
 p(\beta_5 > 1.0) &= p(\beta_5 - 0.9 > 0.1) \\
 &= 1 - \Phi\left[\frac{0.1}{\sigma_{\beta_5}}\right] = 1 - \Phi(5) \quad (A-12)
 \end{aligned}$$

From the table of  $\Phi(t)$ ,

$$\Phi(t) = 1.0000 \quad , \quad t > 3.9 \qquad (A-13)$$

Hence,  $p(\beta_5 > 1.0) = 0.0000$

TABLE A-1

## C        MAINLINE -- E.P.

C        MAINLINE -- E.P.        EXPANDED PROBLEM

C        THIS PROGRAM IS STEP 1 OF A TWO STEP PROCESS  
 C        OPTIMIZATION PROCEDURE. IN THIS STEP, PROCESS DATA  
 C        ARE READ IN AND TABLEAU ENTRIES GENERATED. L.P. IDENT  
 C        -IFICATION DATA ARE READ IN AND THE L.P. PROBLEM IS  
 C        WRITTEN OUT (ON LOGICAL UNIT 7) IN A FORM SUITABLE FOR  
 C        INPUT TO IBM'S MPS/360 MATHEMATICAL PROGRAMMING  
 C        PACKAGE.

## C                                - DEFINITIONS -

C        FX(K)                -KTH EXTERNAL FRESH FEED  
 C        G(J,K)                -TOTAL FEED OF COMPONENT J TO UNIT K  
 C        P(J,K)                -COMPONENT J OF THE KTH EXTERNAL PRODUCT  
 C        X(J)                -THE VARIABLES OF THE L.P. PROBLEM

## C                                - VARIABLE LIST -

## C        INPUT VARIABLES -

C        A(I,J,K)                -FRACTION OF G(I,J) WHICH GOES TO UNIT K  
                               -NAGIEV OR RECOVERY FACTOR  
 C        CINS(I,J,K)            -COEFFICIENT OF G(J,K) IN THE ITH CON-  
                               STRAINT  
 C        CON(I)                -FRACTION OF G(1,3) WHICH WOULD BE CON-  
                               VERTED TO ( OR DISAPPEAR FROM) COMPONENT  
                               I IN UNIT 3 IF THE SELECTIVITY OF THE  
                               CATALYST WERE 1.0  
 C        CPROD(I,J,K)           -COEFFICIENT OF P(J,K) IN THE ITH CON-  
                               STRAINT  
 C        CREDVA(I,K)            -COEFFICIENT OF FX(K) IN THE ITH CON-  
                               STRAINT  
 C        D(I,J,K)                -FRACTION OF G(I,K) WHICH LEAVES THE  
                               PROCESS AS EXTERNAL PRODUCT P(I,J)  
 C        FBND(I,1)                -BOUND ON FX(I)  
 C        FBND(I,2)                -FLAG INDICATING TYPE OF BOUND  
                               -SAME DEFINITION AS NBT

## C MAINLINE -- E.P. ... (CONT'D)

C FDCOST(I,J) -COST OF COMPONENT I OF FX(J)  
 C  
 C GBND(I,K,1) -BOUND ON G(I,K)  
 C GBND(I,K,2) -FLAG INDICATING TYPE OF BOUND  
 C -SAME AS NBT  
 C  
 C NCODE(I) -FLAG INDICATING TYPE OF ITH CONSTRAINT  
 C -1 - GREATER THAN OR EQUAL TO  
 C 0 - EQUALITY  
 C +1 - LESS THAN OR EQUAL TO  
 C  
 C NCOMP -NUMBER OF COMPONENTS  
 C  
 C NCON -NUMBER OF CONSTRAINTS (EXCEPT MATERIAL  
 C BALANCE CONSTRAINTS)  
 C  
 C NG -NUMBER OF UNITS - INCLUDING STREAM  
 C SPLITTERS  
 C  
 C NF -NUMBER OF EXTERNAL FRESH FEEDS  
 C  
 C NPRO -NUMBER OF EXTERNAL PRODUCT STREAMS  
 C  
 C PBND(I,J,1) -BOUND ON P(I,J)  
 C PBND(I,J,2) -TYPE OF BOUND ON P(I,J)  
 C -SAME AS NBT  
 C  
 C RNGE(I) -OTHER LIMIT ON RANGE OF RHS(I)  
 C  
 C RHS(I) -RIGHT HAND SIDE OF CONSTRAINT I  
 C  
 C SEL -SELECTIVITY OF CATALYST IN UNIT 3  
 C  
 C VALPRO(I,J) -VALUE OF PRODUCT STREAM P(I,J)  
 C  
 C Y(I,J,K) -FRACTION OF FEED FX(K), FED TO UNIT K,  
 C WHICH IS COMPONENT I  
 C  
 C TABLEAU VARIABLES -  
 C  
 C BOUND(K) -THE BOUND ON THE KTH VARIABLE (COLUMN)  
 C IN THE LINEAR PROGRAMMING PROBLEM  
 C  
 C CC(J,K) -THE COEFFICIENT IN THE JTH ROW, KTH  
 C COLUMN IN THE COEFFICIENT MATRIX OF THE  
 C SET OF CONSTRAINTS  
 C  
 C CZ(K) -THE COST OF THE KTH VARIABLE  
 C -THE OBJECTIVE FUNCTION  
 C  
 C M -THE NUMBER OF ROWS IN THE L.P.PROBLEM

## C MAINLINE -- E.P. ... (CONT'D)

C EXCLUDING THE OBJECTIVE FUNCTION ROW  
 C -THE NUMBER OF CONSTRAINTS EXCLUDING  
 C RANGES AND BOUNDS  
 C  
 C N -THE NUMBER OF COLUMNS IN THE L.P. PRO-  
 C BLEM EXCLUDING LOGICAL VARIABLES AND THE  
 C RIGHT HAND SIDE  
 C  
 C R(J) -THE RIGHT HAND SIDE OF THE JTH CON-  
 C STRAINT  
 C  
 C RANGE(K) -IF R(K) MAY VARY OVER A RANGE OF VALUES,  
 C R(K) IS ONE LIMIT ON THE RANGE (UPPER OR  
 C LOWER) AND RANGE(K) IS THE MAGNITUDE BY  
 C WHICH THE RIGHT-HAND SIDE MAY VARY FROM  
 C THE LIMIT PREVIOUSLY SPECIFIED  
 C  
 C CONTROL VARIABLES -  
 C  
 C MM -THE NUMBER OF ROWS CC IS DIMENSIONED FOR  
 C -USED FOR ADJUSTABLE DIMENSIONS  
 C  
 C NB -INPUT FLAG INDICATING THE PRESENCE OF A  
 C BOUND VECTOR  
 C NB=0 - NO BOUNDS  
 C NB=1 - BOUNDS REQUIRED  
 C  
 C NBT(K) -FLAG INDICATING TYPE OF BOUND  
 C 0 - NO BOUND ON THIS COLUMN  
 C 1 - LOWER BOUND  
 C 2 - UPPER BOUND  
 C 3 - FIXED VALUE  
 C 4 - FREE VARIABLE  
 C 5 - LOWER BOUND IS -INFINITY  
 C 6 - UPPER BOUND IS +INFINITY  
 C  
 C NN -NUMBER OF COLUMNS CC IS DIMENSIONED FOR  
 C -USED FOR ADJUSTABLE DIMENSIONING  
 C  
 C NR -INPUT FLAG INDICATING PRESENCE OF RANGE  
 C VECTOR  
 C NR=0 - NO RANGE VECTOR  
 C NR=1 - RANGE VECTOR REQUIRED  
 C  
 C NSIG(K) -FLAG INDICATING THE TYPE OF THE KTH  
 C CONSTRAINT IN THE TABLEAU  
 C -1 - GREATER THAN OR EQUAL TO  
 C 0 - EQUALITY  
 C +1 - LESS THAN OR EQUAL TO

### 3. DOCUMENTATION

#### 3.1 Procedure

Linear programming was used to find optimal solutions to the specific optimization model for the butadiene process. The form of the model transformation equations used is slightly different (in equation order only) but will be documented by comment cards in the appropriate printouts.

The procedure used consists of two basic steps: generation of the optimization model in a form suitable for input to MPS/360, and solution of the optimization problem by MPS/360. The first involves standard Fortran programming and job control; the second requires a knowledge of MPS/360 procedures and appropriate job control language. A typical set of O.S. control cards required for an MPS/360 run are listed in table B-5.

Details of the procedure, including definition of variables, are documented by comment cards in the printout section: Subroutine INPUT (NB,NR) is documented in Appendix C.

#### 3.2 Input-Output

The Fortran model generation step requires input of the model data and MPSDAT data. The model data required appears in Appendix C, table C-1, MPSDAT data are listed

in tables B-1 and B-2. The Fortran programs generate MPS/360 data defining the appropriate optimization problem. These data are listed in tables B-3 and B-4.

The generated MPS/360 data are read (for the programs documented here, from cards), and the L.P. problem solved. The MPS/360 printout is extensive and not included here. The results are summarized in table 9.

### 3.3 Comments

MPS/360 proved to be an easy-to-use, efficient and accurate procedure. Additional features of the package were required to continue analysis but were not implemented at the time they were needed. For this reason, the remainder of the analysis was done using a simple two-phase simplex algorithm written in Fortran. However, there is no comparison in accuracy or efficiency; every effort should be made to use MPS/360 or a comparable procedure for large problems.

## APPENDIX C

## TABLE C - 3

## VARIABLE DEFINITIONS

## MODEL DATA READ BY INPUT

## - DEFINITIONS -

|        |  |
|--------|--|
| FX(K)  | -KTH EXTERNAL FRESH FEED                 |
| G(J,K) | -TOTAL FEED OF COMPONENT J TO UNIT K     |
| P(J,K) | -COMPONENT J OF THE KTH EXTERNAL PRODUCT |
| X(J)   | -THE VARIABLES OF THE L.P. PROBLEM       |

## - VARIABLE LIST -

## INPUT VARIABLES -

|              |   |
|--------------|---|
| A(I,J,K)     | -FRACTION OF G(I,J) WHICH GOES TO UNIT K<br>-NAGIEV OR RECOVERY FACTOR  |
| CINS(I,J,K)  | -COEFFICIENT OF G(J,K) IN THE ITH CON-<br>STRAINT   |
| CON(I)       | -FRACTION OF G(1,3) WHICH WOULD BE CON-<br>VERTED TO ( OR DISAPPEAR FROM) COMPONENT<br>I IN UNIT 3 IF THE SELECTIVITY OF THE<br>CATALYST WERE 1.0 |
| CPROD(I,J,K) | -COEFFICIENT OF P(J,K) IN THE ITH CON-<br>STRAINT   |
| CREDVA(I,K)  | -COEFFICIENT OF FX(K) IN THE ITH CON-<br>STRAINT  |
| D(I,J,K)     | -FRACTION OF G(I,K) WHICH LEAVES THE<br>PROCESS AS EXTERNAL PRODUCT P(I,J)  |
| FBND(I,1)    | -BOUND ON FX(I)   |
| FBND(I,2)    | -FLAG INDICATING TYPE OF BOUND<br>-SAME DEFINITION AS NBT   |
| FDCOST(I,J)  | -COST OF COMPONENT I OF FX(J)   |
| GBND(I,K,1)  | -BOUND ON G(I,K)  |
| GBND(I,K,2)  | -FLAG INDICATING TYPE OF BOUND<br>-SAME AS NBT  |

TABLE C - 3 ...CONT'D

|   |             |  |
|---|-------------|--|

### 3. DOCUMENTATION

Subroutine INPUT reads in the model data and stores it in the unlabelled COMMON block. The variables and arrays appearing there are defined in table C-3. Subroutine INPUT was developed for model data input to the MPS/360 data generation programs of Appendix B. Advantage was taken of MPS/360 features which allow specification of bounds on variables, and ranges on the requirements, enabling a reduction in the number of constraints. The variable SEL was required in an earlier formulation of the model, and is normally set to 1.0.

The detailed procedure used is documented in the subroutine listings. A listing of the model data required for the butadiene process appears as table C-1. Subroutine INPUT monitors its progress, writing a summary of data read. This summary appears as table C-2.

A better utilization of storage space is possible, but this improvement would require an effort unwarranted for this study.

Subroutine INPUT uses IBM's subroutines MINV and ARRAY (32) for matrix inversion.

### 3. DOCUMENTATION

#### 3.1 Definition of Variables

Communication between CANON, TPHSIM, LPSOL and the calling program is via the COMMON block /LP/. The variables located there are:

|             |   |  |
|-------------|---|--|
| CON (I,J)   | - | constraint coefficient matrix<br>(destroyed)   |
| RHS (I)     | - | constraint requirement vector<br>(destroyed)   |
| CZ (J)      | - | objective function coefficients  |
| VNAME (J,.) | - | variable names for output via<br>LPSOL   |
| X (J)       | - | optimal solution values of variables<br>x(N+1) = optimal objective function<br>value |
| NCODE (I)   | - | code vector indicating constraint<br>type  |
|             |   | NCODE (I) = +1    - <u>&gt;</u>  |
|             |   | NCODE (I) = 0    -    =  |
|             |   | NCODE (I) = -1    - <u>&lt;</u>  |
|             |   | NCODE (M+1) = problem type, <0 - min   |
| M           | - | no. of constraints   |
| N           | - | no. of variables (destroyed)   |
| NBAS (J)    | - | internal code indicating locational<br>variables in the basis. For NBAS (J)=I,       |

$I > 0$ , the  $j^{\text{th}}$  variable is in the basis at level  $\text{RHS}(I)$

NPH                    -     internal code indicating phase no.  
 NS                    -     on exit, solution status code.  
                       NS = 0 - If an optimal solution  
                       was reached.

These are the definitions of variables on entry to or (where appropriate) exit from the simplex algorithm subroutines. Those variables destroyed during computation are so indicated.

### 3.2 Input - Output

Subroutine CANNON requires that the optimization problem be specified via the objective function coefficient vector  $\text{CZ}(J)$ , the constraint coefficient matrix  $\text{CON}(I,J)$ , the requirements vector  $\text{RHS}(I)$ , the constraint and the problem type code vector  $\text{NCODE}(I)$ , the no. of constraints  $\text{AA}$ , and no. of variables  $N$ . The optimal solution variable and objective function values are placed in  $\text{X}(J)$  and written on logical unit 6 if desired (LPSOL input parameter  $\text{kk} = 0$ ). If an optimal solution was not reached, an appropriate error message is written. A sample of the card input of variable names ( $\text{VNAME}(J,.)$ ) required by LPSOL appears in table B-1.

### 3.3 Procedure

The procedure followed is that suggested by Dantzig (25). Subroutine CANON prepares the tableau for the simplex method, subroutine TPHSIM solves the L.P. problem using the two-phase simplex method and LPSOL handles the solution output.

## 2. DOCUMENTATION

Subroutines INIT, COEFF and CONT2 generates the standard form of the reduced optimization model and specifies the entries in the COMMON block /LP/, required for solution by the two-phase simplex algorithm (Appendix D).

Subroutine INIT modifies the model data read by INPUT by converting any ranges specified on the requirements vector to additional constraints.

Subroutine COEFF generates the coefficients of the required transformation equations:

$$\underline{g} = \underline{B}^{-1} \underline{f_x} \underline{Y^*} \quad (B-1)$$

$$\underline{pr} = \underline{T^*} \underline{B}^{-1} \underline{f_x} \underline{Y^*} \quad (B-2)$$

and stores them in arrays BIY and DBIY. The matrix inverse  $\underline{B}^{-1}$  is required. So doing for the inverse by partitioning the matrix enables more efficient calculation of the inverse since  $\underline{B}$  is sparse, and, for this process, block lower triangular.

Subroutine CONT2 generates the objective function and constraint matrix for the reduced problem, converting bounds into additional constraints, and stores the required information in the COMMON block /LP/.

## APPENDIX F

### DETERMINISTIC DECISION, PATTERN SEARCH

### 3. DOCUMENTATION

#### 3.1 Pattern Search - BPSH,BPSOUT

Subroutine BPSH performs a Hooke-Jeeves pattern search, as described by Wilde and Beightler (20), modified to allow for the specification of upper and lower bounds. Possible areas of difficulty are saddle points and resolution valleys.

BPSH seeks to minimize a nonlinear function of from one to five variables. It requires two additional subroutines: FCT, for the function evaluation given a specified argument, and BPSOUT for intermediate communication of search progress if desired. The variables in the parameter list are described below; those which must be defined prior to calling BPSH are marked with an asterisk.

FCT\*      - name of external subroutine used for function evaluation. It calculates the function value F,

given an N dimensional argument vector ARG.

Parameter list: (F,ARG,N).

- B\*        - initial argument vector, dimension N
- on return, B(1) holds min. function value
- DX\*       - initial step size vector, dimension N
- T         - temporary head vector
- on return, argument vector corresponding  
          to min. function value, dimension N
- BND\*      - lower and upper bounds on argument, dimension  
          2 x N
- EPS\*      - test value representing expected absolute  
          error
- N\*        - number of variables
- MIT\*      - maximum no. of iterations (cycles)
- IER        - convergence flag
- = -1        , no convergence in MIT iterations
- = 0        , search continuing
- > 0        , convergence in IER iterations

Subroutine BPSOUT is used to print the status of the search as it progresses if desired. The parameter list requires information as follows:

- F         - current function value
- B         - current search base (initial temporary head)
- IT        - current iteration number
- = 0 prior to first search

kk        - flag indicating status of pattern  
           = 1    - continuing as usual  
           = 2    - interrupted, on first interruption  
                  pattern is destroyed, subsequent consecutive  
                  interruptions, stepsize is halved.

k         - flag indicating step size has been halved  
           = 0       no change  
           = 1       halved

IER       - as above

### 3.2 VAL,STPRNT

Subroutine VAL calculates an optimal objective function value, F, for the linear optimization problem resulting from specifying the NN variable split factors s(I). In addition to the NN, and S(I), available from the parameter list, the variables in COMMON block /V/ must be specified as follows:

IV        - for I = 1,2, .....NN  
           IV(I,1) = unit no. of I<sup>th</sup> stream splitter  
           IV(I,2) = unit no. destination of first stream  
           IV(I,3) = unit no. destination of second  
                  stream

NFIN      - print code  
           NFIN = -1    print L:P. error messages only  
           NFIN = 0    no output

NFIN = 1    print solutions, all system  
                 variables

NFIN > 1    print solution, decision  
                 variables only.

Subroutine STPRNT calculates and prints the dependent system variable values if required.

Other subroutines required are documented in Appendices D and E.

### 3.3 Mainline -- Deterministic Problem

This program solves the deterministic problem using a combination of pattern search and linear programming as presented in Chapter III, section C. The input data required are: data for pattern search initialization, listed in table F-1, defined in sections 3.1, 3.2; variable names for LPSOL, 21 are required similar to those listed in table D-1; and model data listed in table C-1, defined in table C-3.

The mainline prints a summary of initial conditions and BPSOUT summarizes intermediate search results - these are listed in table F-2. The optimal solution summary appears as table 9.

Subroutines required are documented as follows:

INPUT - Appendix C;    INIT - Appendix E;    VAL,BPSH -  
Appendix F.

#### 4. VERIFICATION OF SOLUTION

The solution was verified by solving the deterministic problem starting from a variety of initial conditions (split factors). The results are summarized in table F-3. As can be seen,  $a(i,14,1)$  is consistently 0.088 rather than 0.09 as above. This is probably the result of a resolution valley - a supposition supported by the low sensitivity shown by this factor in the sensitivity analysis.

### 3. DOCUMENTATION

#### 3.1 SIN

This subroutine reads data specifying a problem perturbation and modifies the model data (stored in unlabelled COMMON) accordingly. The original model data may be restored by entering the subroutine at its second entry point, SOUT (i.e. CALL SOUT)

On each perturbation data card, the following variables may be specified.

N - type of perturbation

= 0 end of data sub set 2nd consecutive

0 indicates end of perturbations

= 1 change A(I,J,k)

= 2 change D(I,J,k)

= 3 change CON(I)

VAL - new value for perturbed parameter

I,J,K - appropriate indices

When the end of the perturbation data set is indicated, an appropriate return is made to the calling program statement number specified in the parameter list.

#### 3.2 OUTPUT, SOP

These subroutines summarize the results of the sensitivity analysis and range analysis. A title card

listing the heading to be printed on the summary is required from input data. The parameter list variables are:

DVAL - reference objective function value

OVAL - optimal objective function value,  
perturbed problem

NL - flag

= 0 for first perturbation

NPRT - No. of perturbation

= 0 for end of perturbations

### 3.3 Mainline -- S.A.

This program performs the sensitivity analyses described in chapter III, section D. The input data required are: model data similar to that listed in table C-1, defined in table C-3, but with optimal split factors; variable names for LPSOL, listed in table D-1; and sensitivity analysis data consisting of a title card and perturbation data. Sensitivity analysis data are listed in tables G-1 and G-2.

The sensitivity analysis summaries printed by OUTPUT appear as tables 11 and 13.

Subroutines required are documented as follows:

INPUT - Appendix C

INIT, COEFF, CONT2 - Appendix E

CANON, TPHSIM, LPSOL - Appendix D

## SIN, OUTPUT, - Appendix G

3.4 Mainline -- R.A.

This program performs the range analysis described in chapter III, section D. The input data required are: model data similar to that listed in table C-1, defined in table C-3, but with optimal split factors; variable names for LPSOL, listed in table D-1; and range analysis data consisting of pattern search initialization data, a title card, and perturbation data. Range analysis data are listed in table G-3.

The range analysis summary printed by SOP appears as table 15.

Subroutines required are documented as follows:

|                 |   |            |
|-----------------|---|------------|
| INPUT           | - | Appendix C |
| INIT            | - | Appendix E |
| VAL,BPSH        | - | Appendix F |
| SIN,SOP         | - | Appendix G |
| BPSOUT for BPSH | - | Appendix G |

### 3. DOCUMENTATION

#### 3.1 ECOST

Subroutine ECOST performs a Monte Carlo simulation to estimate the expected cost of uncertainty in specified model parameters, controlling the generation of random samples, ensuring accuracy as outlined in Appendix A, calculating the required statistics, and printing a summary of the results. The variables in the COMMON block /EC/ are described below; those which must be defined prior to entry are marked with an asterisk

|           |   |
|-----------|---|
| RM(I)*    | expected value, $I^{\text{th}}$ sensitive parameter   |
| S(I)*     | variance, $I^{\text{th}}$ sensitive parameter   |
| AT(I)*    | upper limit - $I^{\text{th}}$ sensitive parameter   |
| SUM(J)    | workspace   |
| STAT(J)   | storage of statistics   |
| ALPHA*    | $\alpha$ - defined Appendix A, section 1  |
| DELTA*    | required precision of estimate  |
| CONF*     | confidence level required   |
| NTS(L,8)* | sensitive parameter definition, $L^{\text{th}}$<br>parameter(NTS L,1) - type of base<br>parameter . |
|           | = 1        - a(I,J,K)   |
|           | = 2        - a(i,J,K)   |

= 3        - d(I,J,K)

= 4        - d(i,J,K)

= 5        - CON(I)

NTS (L,5) - type of coupled parameter  
as above

= 0        - no coupled parameter

NTS (L,2) , NTS (L,6)    - I

NTS (L,3) , NTS (L,7)    - J

NTS (L,4) , NTS (L,8)    - K

NSF\*        no. of sensitive parameters  
MAXSAM\*     maximum no. of samples this run  
NINSAM\*     minimum no. of samples before calculating  
any statistics  
NSAM\*       no. of samples taken  
IX           odd integer for random number generator  
NREJ        no. of samples rejected.

### 3.2 EVAL, AVAL, INIT2, REFEED

These subroutines are adequately documented by comment cards included with the listings. Subroutine AVAL uses IBM's subroutine RM (32) for random number generation.

### 3.3 Mainline E.C.

This program estimates the expected cost of uncertainty using Monte Carlo simulation as presented in chapter III, section F, and Appendix A, section 1.

The input data required are: model data similar to that listed in table C-1, defined in table C-3, but with optimal split factors; variable names for LPSOL, listed in table D-1; and expected cost estimation data as listed in table H-1. The mainline produces a summary of initial conditions, which appears as table H-2. Examples of the detailed sample results produced by EVAL appear as table H-3 and a summary listing of sample results produced by ECOST appears as table H-4. The summary of expected cost estimation results appears as table 18.

Subroutines required are documented in this appendix or as follows:

|       |   |            |
|-------|---|------------|
| INPUT | - | Appendix C |
| INIT  | - | Appendix E |
